The final copy of this thesis has been examined by the signatories, and we find that both the content and the form meet acceptable presentation standards of scholarly work in the above mentioned discipline.

Koblesky, Theodore (Ph.D., High Energy Nuclear Physics)

Measurement of Elliptic Flow in p+Au Collisions at  $\sqrt{s_{NN}} = 200$  GeV using the PHENIX Detector  
at RHIC

Thesis directed by Professor James Nagle

Quark Gluon Plasma (QGP), a hot and dense state of matter in which quarks are not confined inside hadrons, is thought to be the same as the universe approximately one microsecond after the big bang. In Au+Au collisions at  $\sqrt{s_{NN}} = 200$  GeV at the Relativistic Heavy Ion Collider (RHIC) and Pb+Pb collisions at  $\sqrt{s_{NN}} = 2.76$  TeV at the Large Hadron Collider (LHC), QGP has been discovered to have unique properties, such as its opacity to color charges and the fact it behaves like a near-perfect fluid. Collective behavior in the form of a substantial elliptical azimuthal anisotropy ( $v_2$ ) in the momentum distribution of final state particles has been observed, indicating a strongly-coupled, hydrodynamically flowing medium. Recently, features of collectivity have been detected in high-multiplicity, small collision systems thought to be too small to produce QGP, such as  $^3\text{He}+\text{Au}$  and  $d+\text{Au}$  at  $\sqrt{s_{NN}} = 200$  GeV,  $p+\text{Pb}$  at  $\sqrt{s_{NN}} = 5$  TeV, and in  $p+p$  at  $\sqrt{s} = 13$  TeV events. In order to constrain models seeking to describe this phenomena, collision systems with distinct initial collision geometries were run at RHIC:  $^3\text{He}+\text{Au}$  for triangular geometry,  $d+\text{Au}$  for elliptical geometry, and  $p+\text{Au}$  for circular geometry. This thesis is the completion of that set of three measurements, by measuring  $v_2$  in the  $p+\text{Au}$ . Comparisons of  $v_2$  in the three collision systems and various theoretical models are made.

## Tables

### Table

1.1	All four of the fundamental forces and the effective strengths of each relative to gravity. Gravity is not covered by the SM but is included for completeness. . . . .	2
3.1	An example Run15 $p$ +Au 200 GeV relevant trigger configuration and parameters. A trigger's scale down number reduces its rate by $1/(1+\text{scale down})$ . . . . .	55
3.2	Some relevant RHIC parameters from Run 15. . . . .	57
4.1	Quality categorization of CA tracks, as a function of PC1 and DC wire hits. The quality parameters used in this analysis are 31 and 63. . . . .	63
4.2	Quality categorization of CA tracks, as a function of DC wire momentum information. The quality parameters used in this analysis are 31 and 63. . . . .	64
4.3	Central Arm Track Cuts. . . . .	66
4.4	. . . . .	72
4.5	Systematic uncertainties given as a percent of the $v_2$ measurement. Note that the non-flow contribution is $p_T$ dependent and the value here quoted corresponds to the highest measured $p_T$ . . . . .	88
5.1	Dataset Variables Comparison listed in order: center of mass energy per nucleon, centrality, mid-rapidity charged particle multiplicity per unit of psuedo-rapidity from [6], year, trigger (as defined in section 2.2.4) particle sample, trigger particle acceptance, event plane determination, $\Psi_2$ Resolution, condition of available non-flow estimate. .	95

5.2 Initial eccentricity $\varepsilon_2$ of small systems at $\sqrt{s} = 200$ GeV for 0–5% centrality from Monte Carlo Glauber initial conditions smeared with a two-dimensional Gaussian of width $\sigma = 0.4$ fm, and IP-Glasma initial conditions. . . . .	98

## Figures

### Figure

1.1	The fundamental particles of the SM arranged to highlight flavor (horizontal) and charge (vertical) patterns among the particles. These are thought to be the smallest discrete pieces of matter which make up everything else in the universe [13]. . . . .	2
1.2	The strong coupling $\alpha_s$ as a function of energy or the square root of the energy or momentum transfer $Q$ . [14]. . . . .	4
1.3	Parton distribution functions (PDF) of the the momentum fraction $x$ in the proton extracted from the data taken by the H1 Collaboration. The curves $xS$ , $xg$ , $xu_v$ , and $xd_v$ correspond to PDFs of sea quarks, gluons, up valence quarks, and down valence quarks in the proton. The gluon $g$ and sea $S$ distributions are scaled by a factor 0.01. The uncertainties include experimental (inner) and model (middle) uncertainties and the parametrization variations (outer). [4]. . . . .	5
1.4	QCD phase diagram of with temperature on the y-axis and net baryonic density on the x-axis [15]. . . . .	7
1.5	Disappearance of degrees of freedom through the evolution of the Universe in time and how this affects the fractional drop of temperature compared to red-shift [47]. . .	7
1.6	The energy density $\epsilon$ divided by $T^4$ vs temperature $T$ at the physical value of the light quark mass [17]. . . . .	8
1.7	Relativistic heavy ion collision evolution timeline starting. Three distinct phases and their times are shown as well as the particles produced [29]. . . . .	11

1.8	The $R_{AA}$ vs $p_T$ of $\pi^0$ mesons produced in Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV at RHIC for two different collision multiplicity classes. [8] . . . . .	13
1.9	A diagram of a heavy ion collision. The blue shapes are the two colliding nuclei and the elliptical yellow shape is the collision overlap region which forms the medium. In the next instant of time the two nuclei would travel farther along the collision axis (into and out of the page) and the medium would expand along the direction of the arrows [45]. . . . .	15
1.10	$v_n$ vs $p_T$ for RHIC Au+Au $\sqrt{s_{NN}} = 200$ GeV and for LHC Pb+Pb $\sqrt{s_{NN}} = 2.76$ TeV for mid-peripheral events for harmonic orders $n$ up to five. The colored curves are the hydrodynamic calculations. The $\eta/s$ is the viscosity parameter used in the calculations [26]. . . . .	16
2.1	A diagram demonstrating the relation between initial state geometry being transformed into final state momentum anisotropy. The left depicts two spherical nuclei colliding parallel to the z-axis. The pair of nuclei leave behind an ellipsoidal shaped medium. This ellipsoid hydrodynamically evolves such that it expands along the steepest pressure gradient which corresponds to the transverse direction. The right depicts the elliptical pattern present in transverse momentum distribution of the final state particles after the medium has finished evolving [26]. . . . .	18
2.2	A diagram of the possible initial conditions of heavy ion collisions. The impact parameter is the red line. The language used in heavy ion physics is as follows: the larger the overlap between the colliding nuclei, the more central it is, the smaller the overlap, the more peripheral it is. Adapted from [48]. . . . .	19

2.3	The right plot is 2-D two-particle correlation function for $p+p$ collisions at $\sqrt{s_{NN}} = 7$ TeV for hadrons with the same trigger and associated $p_T$ range of $1.0 <  p_T  < 3.0$ GeV/c for all events [32]. The left plot is 2-D two-particle correlation function for Pb+Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV 0-10%centrality events for trigger hadrons with $3 < p_T^t < 4$ GeV/c and associated hadrons with $2 < p_T^t < 2.5$ GeV/c measured by ALICE [32]. . . . .	22
2.4	The 1-D correlation function in Pb+Pb at $\sqrt{s_{NN}} = 2.76$ TeV for the most central events for trigger hadrons with $2 < p_T^t < 2.5$ GeV/c and associated hadrons with $1.5 < p_T^t < 2$ GeV/c. The 1-D two-particle correlation function is a projection in $0.8 <  \Delta\eta  < 1.8$ from the 2-D correlation function, the 2-D correlation function being similar to that of the right panel of Figure 2.3. The black dotted points are the values of the correlation function and the colored lines are the first five cos Fourier decomposition components. The black dotted line is the sum of these five components [3]. . . . .	23
2.5	Diagram showing from the beams point of view several variables used to characterize events. The spectators are the nucleons which do not participate in the collision, as opposed to the participants which do participate in the collision. The impact parameter denoted as $b$ and $\Psi_{RP}$ is the reaction or participant plane angle. $\phi$ is the standard azimuthal and $\varphi = \phi - \Psi_{RP}$ . Adapted from [48]. . . . .	25
2.6	Glauber Monte Carlo event (Au+Au $\sqrt{s_{NN}} = 200$ GeV with impact parameter $b = 6$ fm) viewed in the transverse panel and along the beam axis in the left and right panels, respectively. The deeper color disks correspond to the participating nucleons [38]. . . . .	29
2.7	Initial energy density distributions (arbitrary units) in the transverse plane in two different heavy-ion collision events for IP-glasma (top) MC-Glauber (bottom) models [51]. . . . .	31

2.8 An example time evolution of a ${}^3\text{He}+\text{Au}$ event from the initial state to final state. The color scale indicates the local temperature and the arrows are proportional to the velocity of the fluid cell from which the arrow originates [40]. . . . .	33
2.9 2-D two-particle correlation function for $p+p$ collisions at $\sqrt{s_{NN}} = 7$ TeV for hadrons with $1.0 <  p_T  < 3.0$ GeV/c in high multiplicity events, with greater than 109 charged particles, and for any multiplicity of events are shown in the left and right panels, respectively [32]. . . . .	35
2.10 2-D two-particle dihadron correlation function for $p+\text{Pb}$ collisions for 0-20% and 60-100% centrality events as measured by the ALICE detector in the left and middle panel, respectively. The rightmost panel shows the subtraction of the left panel by the middle panel to remove background. [?] . . . . .	36
2.11 $v_2(p_T)$ for different particles (see legend) in Pb-Pb $\sqrt{s_{NN}} = 2.76$ TeV 10-20% events as measured by the ALICE detector. The $\Delta\eta$ gap at minimum is 0.9 units. The right plot shows the $v_2(p_T)$ for different particles (see legend) in p-Pb $\sqrt{s_{NN}} = 5.02$ TeV for 0-20% events that were subtracted by peripheral 60-100% events. The $v_2$ is extracted directly from the two particle correlation function shown in Figure 2.10.	
<b>add refs</b> . . . . .	37

2.12 Elliptic flow measurements made using the 2nd, 4th, 6th, and 8th multi-particle cumulants, where the 2nd multi-particle is subtracted by peripheral events. Also the Lee Yang zero method non-flow elimination method is shown. These quantities are plotted vs the event multiplicity measured as $N_{trk}^{offline}$ , which is the number of charged particle tracks observed during the offline analysis averaged over $0.3 < p_T < 3.0$ GeV/c and over $ \eta  < 2.4$ . The left panel is $v_2^{sub}\{2,  \Delta\eta  > 2\}$ , $v_2\{4\}$ , and $v_2\{6\}$ in $p+p$ collisions at $\sqrt{s} = 13$ TeV. The middle panel $v_2^{sub}\{2,  \Delta\eta  > 2\}$ , $v_2\{4\}$ , $v_2\{6\}$ , $v_2\{8\}$ , and $v_2\{LYZ\}$ in $p+Pb$ at $\sqrt{s_{NN}} = 5$ TeV collisions. The right panel is $v_2^{sub}\{2,  \Delta\eta  > 2\}$ , $v_2\{4\}$ , $v_2\{6\}$ , $v_2\{8\}$ , and $v_2\{LYZ\}$ in $Pb+Pb$ collisions at $\sqrt{s_{NN}} = 2.76$ TeV. The error bars correspond to the statistical uncertainties, while the shaded regions correspond to the systematic uncertainties [31]. . . . .	39
2.13 $v_n(p_T)$ measured for $d+Au$ and ${}^3He+Au$ at $\sqrt{s_{NN}} = 200$ GeV for 0-5% central events. $v_2$ was measured for both systems and $v_3$ was measured for ${}^3He+Au$ . The grey boxes correspond to systematic uncertainties [7]. . . . .	41
2.14 $v_2(p_T)$ for $d+Au$ and ${}^3He+Au$ at $\sqrt{s_{NN}} = 200$ GeV 0-5% centrality events for $\pi^\pm$ and $p+\bar{p}$ separately. The boxes correspond to the systematic uncertainty [7]. . . . .	41
3.1 A helicopter's view of the accelerator chain in BNL starting at the Tandems (in gold) and ending at the RHIC ring (in blue). STAR and PHENIX can be seen at two of the interaction regions. The ring is 2.38 miles in circumference [55]. . . . .	44
3.2 A cross section diagram of the PHENIX detector from the incoming beam's perspective (top) and a cross section diagram of the PHENIX detector from the top down (bottom). The central arm detectors are not present in the bottom diagram [21]. . . . .	46

3.3	The PHENIX coordinate system. The origin is in the middle of the PHENIX detector at the collision point. North and south are parallel to beam axis. East and west are transverse to the beam axis. Central detectors have a west and an east arm on either side of the beam. Forward detectors have a north and a south arm relative to the origin <b>add ref.</b>	47
3.4	PHENIX magnetic field lines from the MMS, CM, and MMN, (left) and the total magnetic field strength from the CM vs the radial distance from the center of PHENIX at $\phi = 0$ X (right) [12].	48
3.5	Photographs of the BBC detector. The left is of a single detector element consisting of a quartz Cherenkov and a PMT. The right is of one of the BBC arms, consisting of 64 detector elements [22].	49
3.6	A photograph of half of the FVTX. The FVTX are the half disks on either end of the picture (left) and a schematic of the FVTX at a slightly different angle (right). The FVTX is only 20 cm in the $z$ direction from the PHENIX coordinate system origin (the center of each picture) [21].	50
3.7	A diagram of the DC titanium frame which encloses the detector (left) and a diagram of the X, U, and V wires in the DC (right) [22].	51
3.8	Ratio of energy to momentum for all Drift Chamber tracks (dashed-dotted line), and tracks associated with RICH hits (solid line) in Au+Au = $\sqrt{s_{NN}}$ 200 GeV collisions. The $p_T$ range is given in the title [9].	52
3.9	Diagram of a granule. Granules are the building blocks of the PHENIX DAQ. Each detector subsystem has at least one granule.	55
3.10	Diagram of the event builder.	56

3.11 The distribution of BBC charges in $p+\text{Au}$ at $\sqrt{s_{NN}} = 200$ GeV events for different triggers. The black curve is the distribution of charges for the minbias trigger. The blue and red curves are the distributions of charges for the high multiplicity trigger. The red curve being scaled by a factor of 1/40 to show agreement with the black curve. The definition of the top 5% more central events are BBC south charges $\geq 48.0$ . The plot shows the large enhancement of the number of 0-5% centrality events that are gained using the high multiplicity trigger compared to the number of 0-5% centrality from the minbias trigger alone. . . . .	57
3.12 A vector diagram illustrating the yellow and blue beam angle confirmation relative to the PHENIX coordinate system. . . . .	58
3.13 The BBC $z$ -vertex distribution in a typical $p+\text{Au}$ run for different triggers as described in Table 3.1. The teal curve is the BBC(>0 PMTs) novertex trigger, the blue is the BBC(>0 PMTs), and the magenta is the BBC(>0 PMTs) narrowvertex. . . . .	59
3.14 A Monte Carlo Glauber $d+\text{Au}$ event display. Each circle is a nucleon. The red nucleons are from the projectile (deuteron) and the green nucleons are participants from the target (gold). Glauber counts even a near miss as a full collision [5]. . . . .	60
3.15 Real data for BBCs charge shown as open circles and MC-Glauber + NBD (top). The colors correspond to the various percentiles relative to the total inelastic $p+\text{Au}$ cross section, from right to left: 0-5%, 5-10%, 10-20%, 20-30%, 30-40%, 40-50%, 50-60%, 60-70%, and 70-84%. The blue and red curves correspond to the minbias trigger efficiency in all inelastic collisions and inelastic collisions producing a particle at mid-rapidity, respectively (bottom). . . . .	61

4.1	Reference coordinate system for the PHENIX detector. The origin is set at the collision point, around which the detector is centered. The beam runs parallel to the (longitudinal) $z$ -axis, where the direction of positive $z$ is defined as <b>north</b> . The <b>east</b> and <b>west</b> directions are defined as perpendicular to the longitudinal direction, where the direction of positive $x$ is defined as west. . . . .	63
4.2	Momentum resolution $\sigma_p/p$ as a function of the reconstructed track momentum, $p$ for simulated single-particle events[1]. . . . .	64
4.3	Transverse momentum $p_T$ distribution of CA tracks in $p$ +Au events at $\sqrt{s_{NN}} = 200$ GeV. High $p_T$ tracks observed correspond to unsubtracted background. . . . .	64
4.4	The distribution of (left) $n0$ , i.e., the number of PMTs fired in the RICH, and (right) $zed$ , i.e., the longitudinal position of tracks in the DC, for CA tracks in 0-5% central $p$ +Au events at $\sqrt{s_{NN}} = 200$ GeV. The structure observed in the $zed$ distribution corresponds to a gap in the detector acceptance. . . . .	65
4.5	The top plots show the PC3 matching $d\phi$ fit in range $1.0 < pT < 1.1$ (GeV/c). The blue and pink lines are single Gaussian fits to the signal and background, respectively, which are combined in the red line. The bottom plots show the result of the $dz$ signalization, done in the same way as for $d\phi$ . . . . .	67
4.6	Distribution of FVTX clusters in $x$ and $y$ for layers 1, 2, 3, and 4 for panels a), b), c), and d), respectively. The color scale corresponds to the number of counts. . . . .	68
4.7	Diagram showing the positions of the PMTs for the BBC-south detector. Rings shown with the same color indicate PMTs at an approximate common radius. . . . .	69
4.8	Intermediate steps involved in calculating the event resolution. (left) Raw difference between the event plane angles for two different detectors. This distribution is triangular because it is the result the cross-correlation of two uniform distributions, $\Psi_2^{FVTX}$ and $\Psi_2^{BBC}$ . (right) The cosine of two times the difference between the two event plane angles. The average of this distribution is used in equation 4.15. . . . .	71

4.9 This is the $\Psi_2$ distribution projected over all z-vertex bins at different steps during the calibration. The top is from the FVTX south and the bottom is from the BBC south. The range of the $\Psi_2$ resolution is from $-\frac{\pi}{2}$ to $\frac{\pi}{2}$ because of the periodicity. The raw (in red) $\Psi_2$ distribution has a sinusoidal shape. The re-centered (in green) $\Psi_2$ distribution moves the mean. The flattened (in blue) $\Psi_2$ distribution spreads out the counts so that there is uniformity. Each calibration step preserves the integral. . . . .	74
4.10 First attempt at measuring $v_2(p_T)$ with the event plane as calculated with the FVTXs (top left) and the BBCs (bottom left) in the $p+\text{Au}$ at $\sqrt{s_{NN}} = 200$ GeV dataset, using the default resolution as shown in Table 4.4. The black points show $v_2$ measured using all CNT tracks. The blue and red points show $v_2$ measured using only tracks in the west and east arms, respectively. The ratios are fit with a constant, whose value is shown in the legend. . . . .	75
4.11 Diagram illustrating the angle at which the yellow and blue beams collide relative to the longitudinal $z$ -axis of the detector. The yellow beam corresponds to the Au (south-going) beam, and blue corresponds to the proton (north-going) beam. Due to a necessity of running $p+\text{Au}$ collisions at $\sqrt{s_{NN}} = 200$ GeV at RHIC, the beams collide at an angle of 3.6 mrad. . . . .	76
4.12 A corrected measurement of $v_2$ as a function of $p_T$ with the FVTXs (top two panels) and the BBCs (bottom two panels) event plane for the $p+\text{Au}$ $\sqrt{s_{NN}} = 200$ GeV dataset. The default resolution as shown in table 4.4 is used. The plotting conventions are the same as described in the caption of Fig 4.10. . . . .	77
4.13 (left) Cartoon diagram illustrating $\eta$ acceptance shift due to a beam offset in one of the FVTXs layers. (right) Pseudorapidity distribution of charged particles from the AMPT Monte Carlo generator for $p+\text{Au}$ $\sqrt{s_{NN}} = 200$ GeV, showing the shift in $\eta$ acceptance. . . . .	78
4.14 The left is the modification of the $\eta$ acceptance as a function of $\phi$ for the FVTX first layer. The right is the calculated correction factor from this modification. . . . .	79

4.15 These four panels show the FVTX $\phi$ dependent cluster weighting when calculating the FVTX event plane for each layer separately for events with a collision vertex in z is around 0. There are some $\phi$ regions where weight factor is outside of the dotted line bounds. This indicates that either there was a severe deficit or excess of clusters measured in the region. Later, we will examine the effect of keeping these regions or cutting them out on the $v_2$ measurement. . . . .	81
4.16 The black is the FVTX weighting and the blue is the analytic weighting. They have good agreement. . . . .	82
4.17 Shown here is BBC the multiplicative weight factor $F$ used when calculating the modified event plane for events where the collision vertex in z is around 0. The y-axis is the weight factor and the x-axis is the PMT number for the BBCs (there are 64 total in the BBCs). . . . .	82
4.18 These plots depict the average PMT charge per event versus $\phi$ in the a) the p+p $\sqrt{s} = 200$ GeV and b) $p+\text{Au}$ $\sqrt{s_{NN}} = 200$ GeV. The PMTs are separated by color, which corresponds to the rings of approximate common radius as shown in Fig 4.7. The left plot shows near uniformity as a function of $\phi$ and ring. However, the right plot shows a significant deviation from uniformity especially for the innermost rings (rings 1 and 2). In addition to the $\phi$ variation for the right plot, the innermost rings have the largest average charge when compared to the other rings. This is in part due to the fact the innermost rings cover the a slightly larger $\eta$ range. However, the innermost rings in the left plot also cover the largest $\eta$ range and do not exhibit this separation in rings. . . . .	83

4.19 Plotted is the FVTXs correction summary where the y-axis is the east/west $v_2$ ratio and the x-axis is the different subset of clusters used to calculate the $v_2$ . The black markers correspond to the default corrections. The red boxes correspond to the corrections with the analytic weighting shown in Fig 4.14. The blue diamonds are the FVTX inverse $\phi$ weighting as shown in section 4.4.1. Finally, the green crosses correspond to the same as the blue diamonds except an additional hot-cold filter of 20% was applied. The first column is using all the FVTXs layers except for the 3rd layer (explained in the text). So the first columns should be approximately the average of columns 2, 3, and 5. Columns 2 through 5 show the ratio calculated from clusters only in that layer. . . . .	85
4.20 Plotted is the BBC correction summary where the y-axis is the east/west $v_2$ ratio and the x-axis is the different subset of PMTs used to calculate the $v_2$ . The black markers correspond to the default corrections. The red boxes correspond to the corrections with the analytic weighting shown in Fig 4.14. Finally, the blue diamonds correspond to the BBC inverse $\phi$ charge weighting as shown in section 4.4.2. The first column is the quantity calculated from all PMTs. Columns 2 through 6 are using PMTs from certain rings as defined in Fig 4.7. Ring 1 is the hardest to correct. The first column should approximately be the average of all the other columns. . . . .	86
4.21 FVTXs $v_2$ event plane measurement corrected with inverse $\phi$ weighting and 20 % cut with FVTXs layer 3 is excluded (top) and BBCs $v_2$ event plane measurement corrected with p+p/p+Au ratio weighting (bottom). . . . .	87
4.22 The distribution of BBC PMT timing values. The x-axis is the difference between the southern BBC PMT $t_0$ - the mean $t_0$ in the south. An example of a normal event (left) and an example pile-up event (right), are shown. . . . .	89

4.23 Plotted here is the 2D profile of a correlation function in $\Delta\eta\Delta\phi$ space of a dijet event. The area in red dotted lines represent the exclusion zone in $\Delta\eta$ , such that the measurement is made only using data from outside of the exclusion zone to reduce non-flow contributions. . . . .	90
4.24 (a) The second order harmonic coefficients $c_2(p_T)$ for long range angular correlations in 0%–5% $p+\text{Au}$ collisions, as well as for minimum bias $p+p$ collisions. The latter are scaled down by the factor $(\sum Q^{\text{BBC-S}})_{p+p} / (\sum Q^{\text{BBC-S}})_{p\text{Au}}$ . (b) The ratio of the two harmonics is plotted with the corresponding statistical errors. . . . .	91
5.1 The $v_2$ measurement of $p+\text{Au}$ at $\sqrt{s_{NN}} = 200$ GeV 0–5% centrality. . . . .	93
5.2 The $v_2$ measurement of $p+\text{Au}$ at $\sqrt{s_{NN}} = 200$ GeV 0–5% centrality with the statistical and systematic errors corresponding to the bars and the boxes respectively. The stars are the same $p+\text{Au}$ points but with the non-flow estimate subtracted rather than treated as a systematic uncertainty. . . . .	94
5.3 $v_2$ of charged hadrons within $ \eta  < 0.35$ in 0–5% $p+\text{Au}$ compared to calculations using the SONIC model match to the same multiplicity as the data. The model calculations have good agreement with the center of the systematic uncertainty bars. . . . .	96
5.4 $v_2$ of charged hadrons within $ \eta  < 0.35$ in 0–5% $p+\text{Au}$ , $d+\text{Au}$ , and ${}^3\text{He}+\text{Au}$ central collisions, compared to hydrodynamic calculations using the SONIC model, matched to the same multiplicity as the data. Note that the data points shown include non-flow contributions, whose estimated magnitude is accounted for in the asymmetric systematic uncertainties. . . . .	97
5.5 The top three panes show the transverse spatial locations of the initial hot spots of the three collision species, $p+\text{Au}$ , $d+\text{Au}$ , and ${}^3\text{He}+\text{Au}$ respectively. The bottom three plots show the resulting medium produced from the overlapping hot spots as well as the resulting particle momentum vector field as calculated from a hydrodynamic model, calculation details in [52] . . . . .	99

5.6 $v_2/\varepsilon_2$ versus $\varepsilon_2$ with the flow coefficient for pions evaluated at $p_T = 1.0$ GeV/c from $p+\text{Au}$ , $d+\text{Au}$ , and ${}^3\text{He}+\text{Au}$ central ( $b < 2$ fm) events (which roughly corresponds to 0–5% centrality). The results are with input parameters $\eta/s = 1/4\pi$ and initial Gaussian smearing $\sigma = 0.4$ fm and a freeze-out temperatures of $T_F = 150$ MeV. Diagrams of two possible $d+\text{Au}$ initial configurations are overlayed on top of the plot. Increasing distance between the two $d+\text{Au}$ nucleons correspond to a larger $\varepsilon_2$ [40]. . . . .	100
5.7 $v_2$ of charged hadrons within $ \eta  < 0.35$ in 0–5% $p+\text{Au}$ , $d+\text{Au}$ , and ${}^3\text{He}+\text{Au}$ central collisions, divided by their corresponding eccentricity $\varepsilon_2$ from Glauber calculations, compared to SONIC calculations of the same quantity. Note that the data points shown include non-flow contributions, whose estimated magnitude is accounted for in the asymmetric systematic uncertainties. . . . .	101
5.8 Centrality dependence of $\varepsilon_2$ calculated in a variety of small collision systems with a variety of models for collision detection [disklike (left), Gaussian (middle), quark-subdivided nucleons with $\sigma_g = 0.3$ fm (right)] [58]. . . . .	102
5.9 Transverse momentum dependence of $v_2$ in central 0–5% (a) $p+\text{Au}$ , (b) $d+\text{Au}$ , and (c) ${}^3\text{He}+\text{Au}$ collisions at $\sqrt{s_{NN}} = 200$ GeV. Theoretical calculations from AMPT, SuperSONIC, and IP-Glasma+Hydro are shown in each panel. Note that the data points shown include non-flow contributions, whose estimated magnitude is accounted for in the asymmetric systematic uncertainties. . . . .	104
6.1 $v_2$ of charged hadrons within $ \eta  < 0.35$ in 0–5% centrality $p+\text{Au}$ , $d+\text{Au}$ , and ${}^3\text{He}+\text{Au}$ at $\sqrt{s_{NN}} = 200$ GeV events, compared with hydrodynamic calculations using the SONIC model, matched to the same multiplicity as the data [28]. . . . .	106
6.2 The total space-time volume as a function of $\sqrt{s_{NN}}$ in heavy ion collisions [34]. . . . .	107

6.3 Calculations of  $v_2(p_T)$   $d+\text{Au}$  events at various  $\sqrt{s_{NN}}$  (given on the upper right of each panel) for AMPT, SONIC, and SuperSONIC models. Note that there are data points in the lower right panel due to the fact that the  $v_2$  in  $d+\text{Au}$  at  $\sqrt{s_{NN}} = 200$  GeV has been measured previously by PHENIX from data taken in 2008 [34]. . . . 108

## Chapter 1

### Physics Overview

In order to give the proper context for the measurement shown in this thesis, an overview of the physical theory relevant to the measurement is given in this chapter. We start with the SM (Standard Model of particle physics), narrow the focus down to QCD (Quantum Chromodynamics), and then narrow the focus even more to a specific state of matter governed by QCD known as QGP (Quark Gluon Plasma). Properties of QGP are discussed including energy loss and elliptic flow. A more comprehensive discussion on the topic of elliptic flow and small collision systems will be presented in Chapter 2.

#### 1.1 The Standard Model

The SM is the best understanding of the fundamental building blocks reality and how they interact. The SM as we know it today has evolved over many years, including the unification of the electromagnetic and weak forces in the late 1960s. The present day SM includes four fundamental forces, listed in Table 1.1, and the fundamental particles, listed in Figure 1.1.

The SM has the capability of making quantifiable predictions which have been shown to be in agreement with experimental measurements to many decimal places. The SM has endured decades of meticulous experimental testing without the need for major revisions, a notable exception being neutrino oscillations. The mathematical framework underpinning the SM is formally known as QFT (Quantum Field Theory) which combines the continuous nature of field physics with the discrete nature of quantum physics. The fundamental symmetries of the SM are given by the combination

Table 1.1: All four of the fundamental forces and the effective strengths of each relative to gravity. Gravity is not covered by the SM but is included for completeness.

Force	Current Theory	Relative Strength	Range [m]	Force Carriers
strong	Quantum Chromodynamics (QCD)	$10^{41}$	$10^{-15}$	gluon
electromagnetic	Quantum Electrodynamics (QED)	$10^{38}$	infinity	photon
weak	Electroweak	$10^{25}$	$10^{-18}$	$Z^0, W^{+/-}$
gravity	General Relativity	1	infinity	graviton

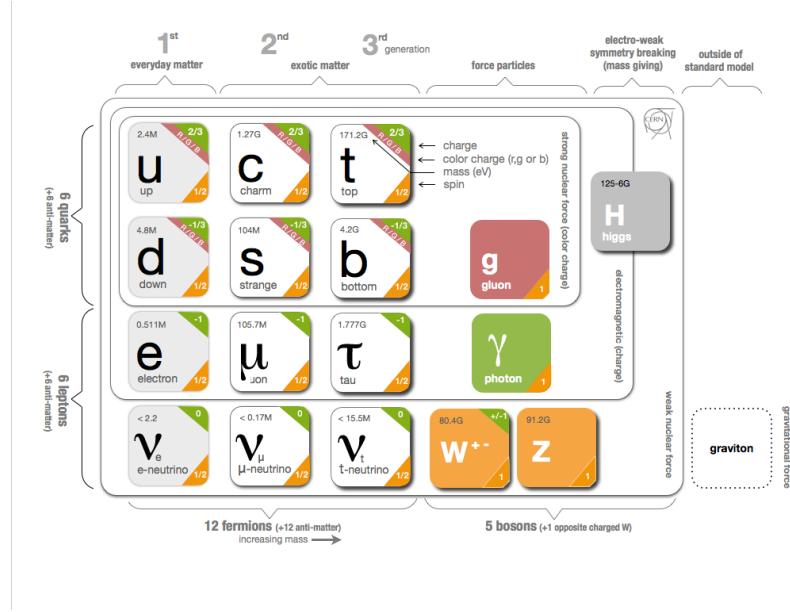

Figure 1.1: The fundamental particles of the SM arranged to highlight flavor (horizontal) and charge (vertical) patterns among the particles. These are thought to be the smallest discrete pieces of matter which make up everything else in the universe [13].

of the  $SU(3) \times SU(2) \times U(1)$  groups as defined in group theory. Each symmetry group represents the symmetry of each of the fundamental forces in the SM such that  $SU(3)$ ,  $SU(2)$ , and  $U(1)$  represent the strong, weak, and electromagnetic forces respectively. As shown in table 1.1, each of the fundamental forces has a quantized theory associated with it. The electromagnetic and weak forces combine into a single theory at high energy, known as the Electroweak Theory. No similar theory which has been experimentally verified has combined strong and electroweak upon writing of this thesis.

Any given interaction described by the SM starts with an initial set of particles, a series of interactions between those particles (which is represented by an exchange of virtual particles), and then a set of final state output particles. Experimentally, the only information available to the experimenter is the list of input particles and output particles. The in-between step of the interaction of the particles is where QFT is used. Theoretical physicists use QFT to calculate the probabilities of each possible interaction diagram given a set of input particles or a set of output particles or both. To complicate things, there are infinite possible interaction diagrams for any given set of inputs and outputs; however, there are always leading diagrams which have the highest probability of occurring. Generally the simpler the interaction diagram, the higher the probability.

In order to make predictions about physical systems dominated by the strong force, like the heavy ion collision systems studied in this thesis, we turn to QCD.

### 1.1.1 Quantum Chromodynamics

Of the fundamental particles which make up the SM, the only seven which interact through the strong force are the six quarks and the gluon. These particles have a unique quantum number named color charge which can be one of three values referred to as red ( $r$ ), green ( $g$ ), and blue ( $b$ ), in an analogy to three colors commonly used to form the basis of light in the visible spectrum. Like the electric charge in QED, each color has a negative value referred to as anti-red ( $\bar{r}$ ), anti-green ( $\bar{g}$ ), and anti-blue( $\bar{b}$ ), making six possible states for the quantum number in total. Gluons have two color charge quantum numbers, one charge and one anti-charge. This fact means gluons interact with themselves, which produces two important effects in QCD: confinement and asymptotic freedom.

In QED, electromagnetic fields decrease with distance away from a point charge. This functional form allows electromagnetically bound states to separate. However in QCD, the self interaction of the gluon means that as two quarks separate, the force between them grows proportionally to the distance between them. As a quark-antiquark ( $q\bar{q}$ ) pair separates, each quark in the pair has so much potential energy that quarks from the vacuum bind to each quark to form two new pairs. The outcome of this effect is that solitary quarks can never be observed in a vacuum, by the time

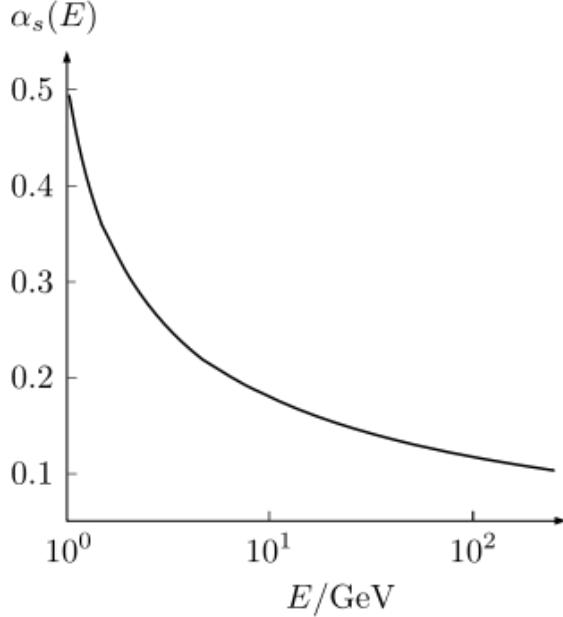

Figure 1.2: The strong coupling  $\alpha_s$  as a function of energy or momentum transfer  $Q$ . [14].

we try to observe them they will have found another particle in the vacuum with which to bind. This means that quarks are confined to zero color charge (or color neutral) bound states. Color neutral bound states are defined as a color state and anti-color state (ex.  $r\bar{r}$ ,  $g\bar{g}$ ,  $b\bar{b}$ ), known as mesons, or a tricolor state (ex.  $rgb$  or  $\bar{rgb}$ ), known as baryons. The list of the two or three quarks which make up color neutral bound state are known as valence quarks. Valence quarks are quarks which determine the quantum number for the hadron in contrast to sea quarks which are  $q\bar{q}$  pairs made from gluon annihilations and fill all the lower states. Quarks and gluons found in hadrons are known as partons, and partons carry a fraction of the hadron's total momentum  $x$ . Partons can have any momentum fraction of the total momentum, but it is most probable that valence quarks have one third of the total momentum where as gluons and sea quarks are more likely to have a much smaller momentum fraction. Figure 1.1.1 shows measured parton distribution functions in the proton, illustrating the difference of the average  $x$  for valence quarks in contrast to sea quarks.

Color neutrality can arise from other combinations of quarks; from combinations of quarks and gluons; or even arrangements of gluons with no valence quarks. The first mentioned combinations

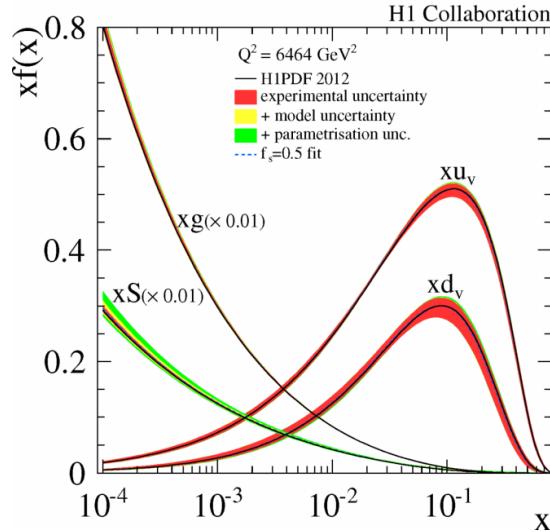

Figure 1.3: Parton distribution functions (PDF) of the the momentum fraction  $x$  in the proton extracted from the data taken by the H1 Collaboration. The curves  $xS$ ,  $xg$ ,  $xu_v$ , and  $xd_v$  correspond to PDFs of sea quarks, gluons, up valence quarks, and down valence quarks in the proton. The gluon  $g$  and sea  $S$  distributions are scaled by a factor 0.01. The uncertainties include experimental (inner) and model (middle) uncertainties and the parametrization variations (outer). [4].

are theoretical color neutral states of four or more quarks which have yet to be experimentally observed. The second and third mentioned combinations are known as exotic mesons or glueballs and there are experiments searching for their signatures.

Another related effect of the self-interaction of the gluon is known as the screening of bare color charges. Once again it is helpful to compare to the familiar effects in QED. In QED, electrically charged pairs from the vacuum screen out the bare electric charge, causing the effective charge to decrease. This effect increases as the distance to the electric charge increases because there is a larger quantity of electrically charged pairs between the observer and the charge. Back to QCD,  $q\bar{q}$  pairs produce the same effect, providing a screening effect on the bare color charge, however short-lived the bare color charges are. Further complications arise when the color-carrying gluon in turn creates an anti-screening effect, which is the larger of the two effects. As one approaches a solitary color charge, the density of gluons becomes so large that the strong force counter-intuitively grows weaker. These screening effects alter the strong coupling constant known as  $\alpha_s$  which is proportional to the local strong force magnitude. Figure 1.1.1, which depicts the  $\alpha_s$  as a function of energy scale,

shows the reduction of  $\alpha_s$  at large energies. This behavior is known as asymptotic freedom because the smaller  $\alpha_s$  is, the more quarks can move freely. Thus, there is an energy threshold where the strong force is weak enough where perturbative calculations are valid. The ability to make valid perturbative calculations for QCD is important for being able to make any in-depth QCD calculations of complex systems. Apart from perturbative QCD calculations, lattice QCD is a non-perturbative approach which is formulated on a lattice of space-time points. Although lattice QCD calculations are computationally complex, physical phenomena such as quark confinement can be treated analytically.

In addition to understanding the unique effects of QCD, understanding the phases of QCD matter is important. Figure 1.1.1 is a phase diagram for quark matter with temperature and net baryonic density on the axes. The type of quark matter which makes up the elements of normal matter is found in the figure under the heading of “Nuclear Matter” which is the state of quarks and gluons for complex, relatively stable bound states known as nuclei. The “hadronic phase” indicates a state of quark matter where bound states of quarks form hadrons but those hadrons behave like a non-interacting gas. At very large baryonic density, the “color superconductivity” phase is where the possible quantum states of quarks and gluons are so full that an example of such a state of matter is a neutron star. Finally, under extreme conditions of temperature and bayonic density, quarks may be deconfined and exist as solitary color charges in a plasma. This phase of matter, known as QGP (Quark-Gluon Plasma), provides a medium where screening effects are dominant and  $\alpha_s$  becomes small enough to allow quarks and gluons to move with relative freedom. Although QGP has been observed by multiple experiments at RHIC (Relativistic Heavy Ion Collider) and LHC (Large Hadron Collider) facilities, the critical temperature at which the phase of quark matter is achieved is still unknown, although some recent experiments place the temperature at 170 MeV or  $1.9 \times 10^{12}$  kelvin, which is much hotter than the center of our sun [59].

Lattice QCD calculations have been done to examine the relationship of the number of massless degrees of freedom and the temperature of the medium as which provide insight in how QGP and the early universe transition into normal matter. Figure 1.1.1 shows a curve of a quantity

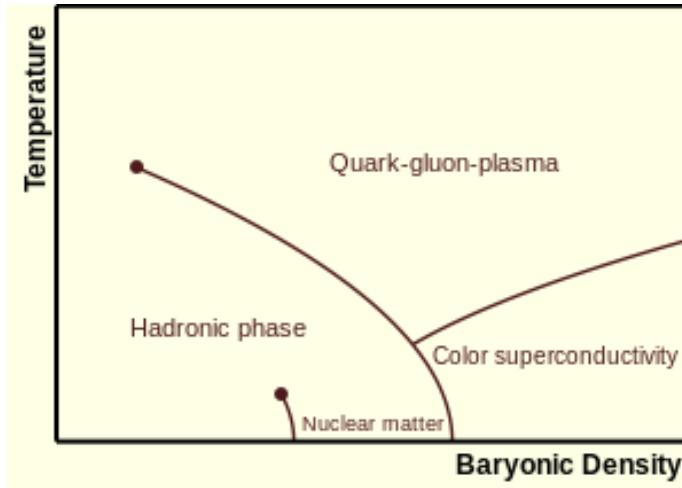

Figure 1.4: QCD phase diagram with temperature on the y-axis and net baryonic density on the x-axis [15].

inversely proportional to the number of massless degrees of freedom. As the temperature drops, the less massive particles annihilate and disappear from the thermal universe, reducing the degrees of freedom. The points on Figure 1.1.1 are the numerical results from a lattice QCD calculation of the Equation of State (EoS). The y-axis for the points on this plot is the energy density divided by the temperature to the fourth power  $\frac{e}{T^4}$  which has been shown to be inversely proportional to the number of massless degrees of freedom [17]. It is noteworthy that the points increase around the transition indicating the disappearance of the degrees of freedom around the transition temperature of the medium.

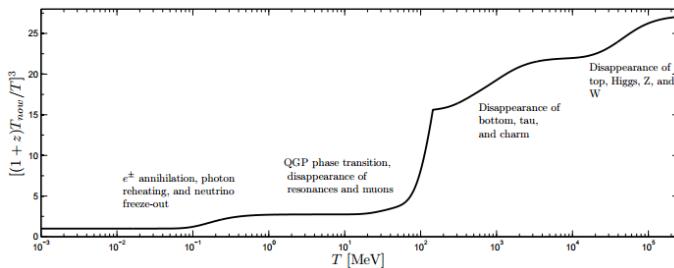

Figure 1.5: Disappearance of degrees of freedom through the evolution of the Universe in time and how this affects the fractional drop of temperature compared to red-shift [47].

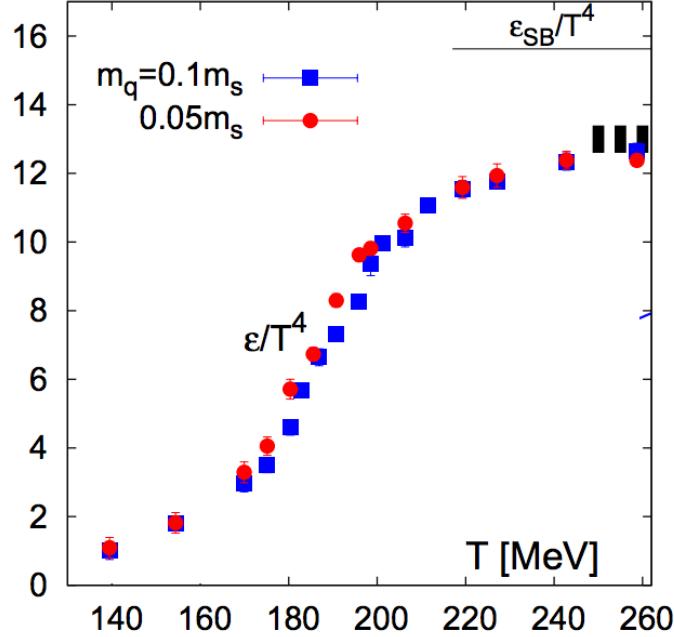

Figure 1.6: The energy density  $\epsilon$  divided by  $T^4$  vs temperature  $T$  at the physical value of the light quark mass [17].

## 1.2 Quark Gluon Plasma

QGP is a new state of matter created in science laboratories and is thought to be the same as the entire early universe approximately one microsecond after the big bang [46]. Thus, studying QGP and its properties in the laboratory can help cosmologists understand the state of the early universe.

The idea of hot hadronic matter was developed in the early 1950s by various physicists including Enrico Fermi [24]. This concept of applying statistical and hydrodynamical models to a strongly interacting particle ensemble ultimately evolved into the theory of QGP. Since then, systematic studies of hot hadronic matter systems have produced a greater understanding of the state of matter hypothesized to be QGP and contributed to its approximate location on the nuclear matter phase diagram in Figure 1.1.1. Many unique properties about this new state of matter have been discovered: for example, QGP behaves like a nearly perfect fluid and is opaque to color charges [10]. Enough research has been done to assemble a probable timeline of how the QGP

evolves.

### 1.2.1 QGP Evolution Timeline

The timeline overview of QGP as made in the laboratory always begins with a high-energy heavy ion collision (Au-Au for example), thus the QGP timeline is embedded in the laboratory timeline. As is the case with all SM interactions, the beginning of QGP starts with initial state observable particles and ends with final state observable particles, although the final state particles may have been produced at different points during the QGP evolution. Although only lasting  $10^{-23}$  seconds or  $10 fm/c$ , several distinct stages occur during this time period and long after the evolution has ceased the final state particles are detected in the experiment one quadrillion QGP lifetimes or one nanosecond later.

At the moment when heavy ions collide relativistically ( $\tau=0$ ), they are length contracted down to flat disks in the lab frame, as seen in Figure 1.2.1. Then, the initial geometry resulting from the shape of the collision overlap region and fluctuations within the nuclei are transformed into the initial energy density of the medium ( $\tau \approx 1 fm/c$ ). At that moment, the hot hadronic matter is thought to be made up of deconfined quarks and gluons in thermal equilibrium, otherwise known as QGP. The system then evolves hydrodynamically, expanding along the pressure gradients present in the initial energy density. At a certain point during this expansion, the medium has cooled down enough in order to form baryons and mesons out of the quark gluon soup in a process known as hadronization. It is important to note that the medium is still in thermal equilibrium at this point although it is no longer known as QGP, instead it is known as hadron gas. Once the medium has cooled down and expanded sufficiently, kinetic freeze-out occurs and the hadron gas becomes a group of particles which have ceased self-interaction ( $\tau \approx 10 fm/c$ ). It is this group of final state particles which can be detected much later ( $\tau \approx 10^{15} fm/c$ ). Although detectable particles escape the medium at all times, the vast majority of particles detected are decoupled at kinetic freeze-out.

Even though all of these phases are of interest to the study of QGP, of particular interest

to QGP researchers is the thermal equilibrium phase when the QGP state is first achieved. It is during this phase where quarks are deconfined, the only time or place in the universe where this occurs. In this environment, features of QCD can be studied, such as how color charges experience energy loss and to what degree is collective behavior observed.

As is referred to in Figure 1.2.1, many types of particles are emitted during the QGP evolution, some of which are emitted before the kinetic freeze-out time. The most common type of particle produced from QGP collisions are baryons and mesons made of up, down, and strange quarks (pions, Kaons, and nucleons), which are in abundant supply during and after the collision. Another type of particle produced from these collisions are photons. QGP being an extremely hot ball of matter, blackbody radiation in the form of thermal photons are emitted and their spectrum can be used to estimate the temperature of the medium. These thermal photons escape the medium due to their lack of interaction with the strong force. Heavy quarks are produced primarily from initial hard parton-parton scatterings, “hard” meaning here that there is a large momentum transfer in the collision. These heavy quarks, such as bottom or charm quarks, often fragment into a shower of less massive particles known as jets as they propagate through space.

### **1.2.2 Emergent Properties of the QGP**

Now that the foundation of the QGP timeline has been established, properties of the medium can be discussed in context. Up to this point in this document, the label of QGP has been applied to state of matter produced from heavy ion collisions, but what evidence is there that this state of matter is a strongly coupled medium made of deconfined quarks and gluons?

Taking into account that the field of high-energy heavy ion collision physics is still evolving, several measured properties of this state of matter have come together to make QGP the prevailing explanation. Among the best observations indicating QGP are particle energy loss and elliptic flow. The observation of hadrons at large  $p_T$  measured at much lower yields than expected imply that the hadrons are experiencing energy loss when interacting with a strongly coupled medium. An elliptic symmetry in the angular distribution of final state particles when viewed along the axis of

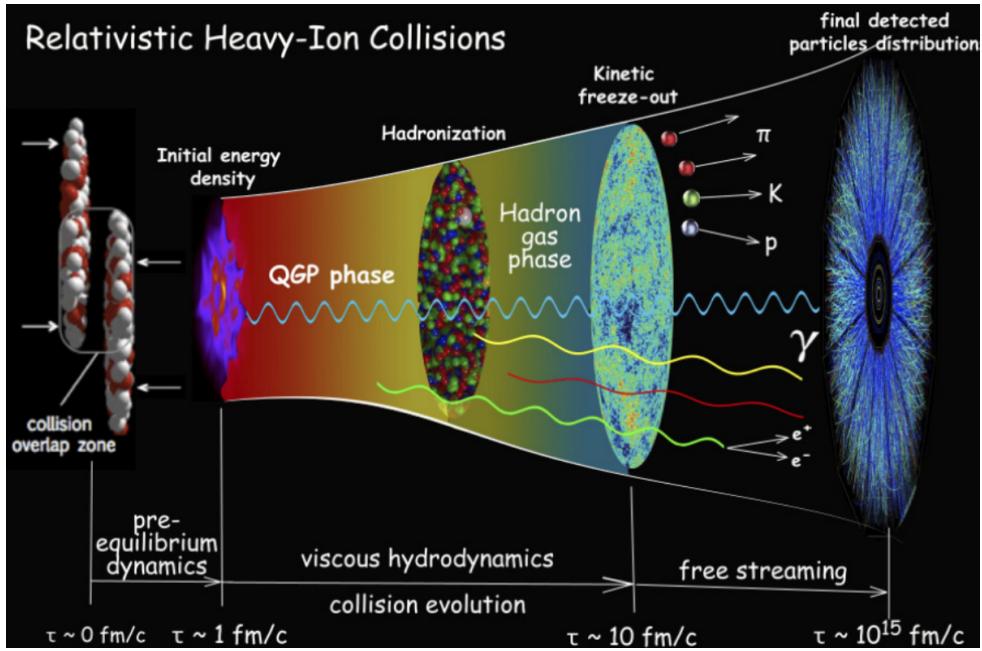

Figure 1.7: Relativistic heavy ion collision evolution timeline starting. Three distinct phases and their times are shown as well as the particles produced [29].

collision has been observed. The translation of initial geometry into long-range angular correlations indicates collectivity in a strongly coupled medium.

#### 1.2.2.1 Particle Energy Loss

In order to study a new medium such as QGP, it is useful to measure things about the QGP relative to a more well known collision system such as p+p. By measuring the relative number of hadrons produced at various transverse momentums in both p+p and heavy ion collisions, QGP medium effects can be teased out.

After the quarks are produced in p+p collisions, they will hadronize and freely travel to the experiment's detector. In heavy ion collisions, the quarks propagate through, and interact with, the QGP, exchanging energy and momentum with the medium along the way. The effect of energy loss on these quarks will modify their yield relative to the yield in p+p collisions. The nuclear modification factor  $R_{AA}$  is the observable used to quantify this modification which is defined for

a given particle as:

$$R_{AA}(p_T) = \frac{dN_{A+A}/dp_T}{\langle N_{coll} \rangle \times dN_{p+p}/dp_T}, \quad (1.1)$$

where  $dN_{A+A}/dp_T$  and  $dN_{p+p}/dp_T$  is the yield of a given particle vs  $p_T$  (transverse momentum) in heavy ion collisions and p+p collisions respectively and  $\langle N_{coll} \rangle$  is the average number of binary collisions for a given class of events. In summary, the  $R_{AA}$  is a ratio for how many particles are produced for the same system with a normalization factor of  $\langle N_{coll} \rangle$  to account for the differences in system size. The  $\langle N_{coll} \rangle$  value is usually determined using Monte Carlo Glauber simulations and will be discussed in more detail in Chapter 2. If the particles do not interact with the medium, the  $R_{AA}$  should be equal to 1.0. A value above 1.0 is interpreted as an enhancement of particles and a value below 1.0 is interpreted as a suppression of particles.

Figure 1.2.2.1 shows a significant suppression in the  $R_{AA}$  vs  $p_T$  of  $\pi^0$  mesons produced in Au+Au collisions at  $\sqrt{s_{NN}} = 200$  GeV at RHIC for large and small sized QGP events, 0-10% central and 80-92% central events respectively (centrality will be discussed in Chapter 2). This large suppression across all  $p_T$  of the  $\pi^0$  for large-sized events as compared to small-sized events indicate energy loss of quarks due to the medium, which is consistent with a strongly coupled medium.

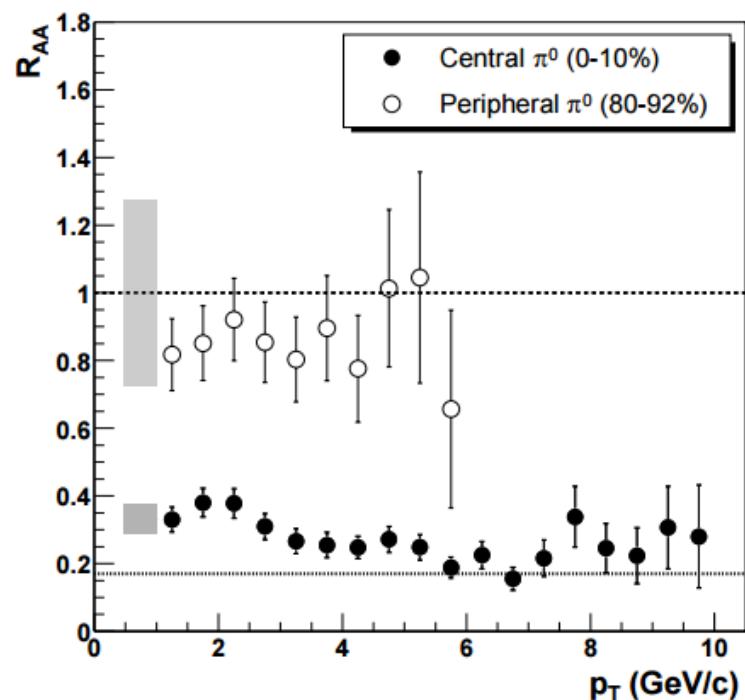

Figure 1.8: The  $R_{AA}$  vs  $p_T$  of  $\pi^0$  mesons produced in Au+Au collisions at  $\sqrt{s_{NN}} = 200$  GeV at RHIC for two different collision multiplicity classes. [8]

### 1.2.2.2 Collective Flow and Azimuthal Anisotropy

Another signal of a strongly coupled medium is collective behavior amongst the constituent particles which make up the medium. By analyzing patterns in the spray of particles emitted from heavy ion collisions, systematic effects can be determined. Nominally there should be no preference in direction for final state particles from a heavy ion collision, the presence of such a preference can indicate correlations among the particles in the medium which can be measured by looking at the azimuthal anisotropy.

Consider the collision of two heavy nuclei as depicted in Figure 1.2.2.2. The overlap region between the two nuclei form an almond shaped region oriented to the plane of the initial collision geometry. After the collision the two nuclei remnants (the blue shapes) no longer participate and the yellow overlap region forms the QGP medium and starts to expand. This energy density distribution gives rise to a larger pressure gradient in the shorter direction rather than the longer direction. The larger the pressure gradient, the more momentum the particles will gain once the medium finishes evolving. This variation in the momentum of final state particles produces systematic effects in the azimuthal (relative to the collision axis) distribution of particles. Therefore, by measuring the azimuthal anisotropy of the final state particles, long-range angular correlation like those present in this in Figure 1.2.2.2 can be measured. The initial state collision geometry being transformed into final state momentum anisotropy indicates collective behavior and elliptical flow of the particles.

In order to quantify the azimuthal anisotropy, the final state particle distribution is Fourier transformed:

$$C(\Delta\phi) \propto 1 + \sum_{n=1} 2v_n \cos(n\Delta\phi)] \quad (1.2)$$

where  $C(\Delta\phi)$  is the correlation function defined by the distribution of the differences between the azimuth of particles from the event relative to other particles in the same event, and  $v_n$  are flow coefficients. The flow coefficients  $v_n$  are proportional to the degree of anisotropy for each harmonic order  $n$ . A  $v_n$  of 0.0 would indicate there is no azimuthal anisotropy. In addition to measuring the  $v_n$  for various systems, a relativistic hydrodynamic calculation can be compared to the data.

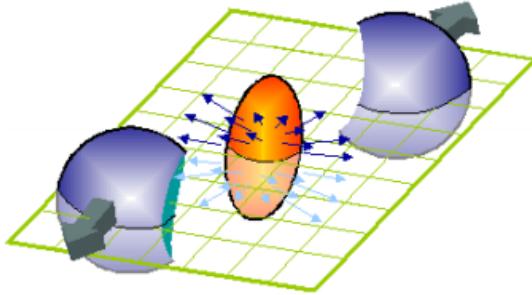

Figure 1.9: A diagram of a heavy ion collision. The blue shapes are the two colliding nuclei and the elliptical yellow shape is the collision overlap region which forms the medium. In the next instant of time the two nuclei would travel farther along the collision axis (into and out of the page) and the medium would expand along the direction of the arrows [45].

Figure 1.2.2.2 shows  $v_n$  vs  $p_T$  for both RHIC and LHC energy heavy ion collisions for mid-peripheral events, such as those depicted in Figure 1.2.2.2. The substantial agreement with hydrodynamic calculations curves indicates a medium which flows.

All of the discussion and results shown in this section have been referring to large collision systems such as Au+Au or Pb+Pb. Small collision systems such as  $p+A$ ,  $d+Au$ , or  $p+p$  were thought to be too small to produce QGP, and thus were ideal as the control experiment to measure background effects of cold nuclei which may obscure the true signal of QGP. However, recent results have shown that small collision systems show signs of QGP formation. Chapter 2 will delve into small collision systems properties and measurements, as well as give a more in-depth discussion in calculating initial conditions and flow coefficients.

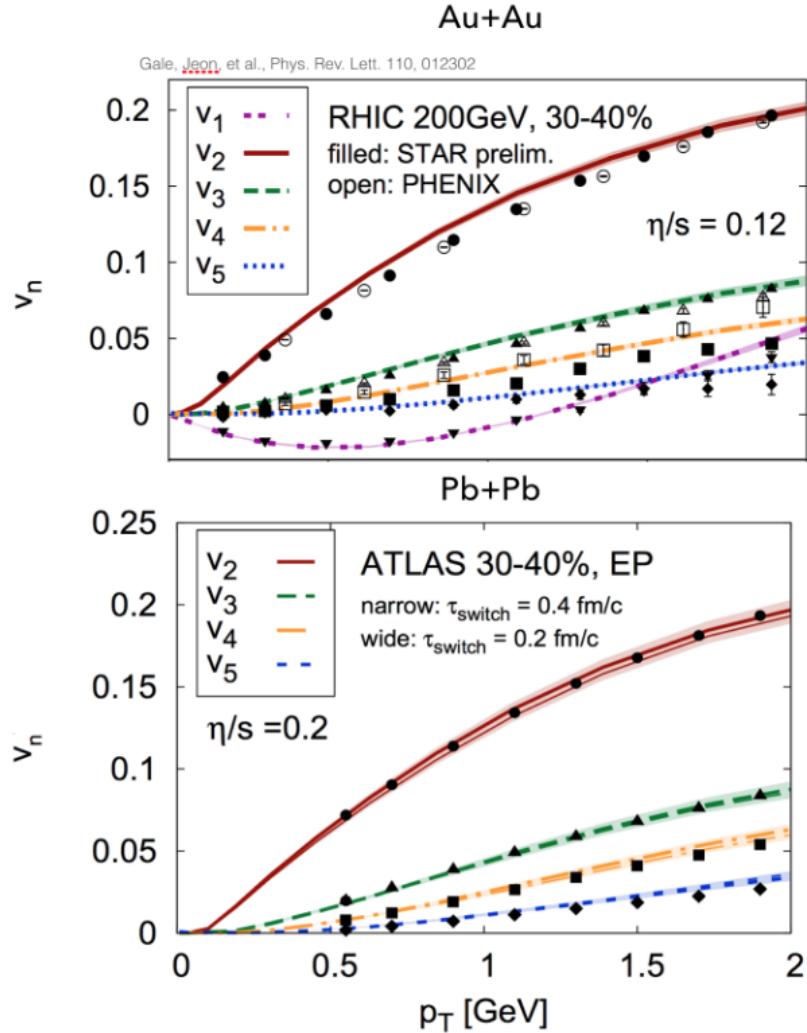

Figure 1.10:  $v_n$  vs  $p_T$  for RHIC Au+Au  $\sqrt{s_{NN}} = 200$  GeV and for LHC Pb+Pb  $\sqrt{s_{NN}} = 2.76$  TeV for mid-peripheral events for harmonic orders  $n$  up to five. The colored curves are the hydrodynamic calculations. The  $\eta/s$  is the viscosity parameter used in the calculations [26].

## Chapter 2

### Collectivity and Flow in QCD Systems

#### 2.1 A Conceptual Understanding of Collectivity and Flow

The observation of collectivity in matter can be a powerful indicator of fundamental properties in that matter. Collectivity means many discrete structures are interacting together to form a whole otherwise known as highly correlated behavior. In high energy heavy ion physics, a common interpretation of this behavior, although not the only interpretation<sup>1</sup>, is of a locally equilibrated medium with bulk properties instead of a group of individually weakly interacting constituent particles. In this case, the medium would be QGP and the bulk properties would be that of a hydrodynamically described fluid: viscosity, density, temperature, etc. The term collectivity is often synonymous with the term hydrodynamic flow or simply flow. In this thesis, the terms will be used synonymously except in specific cases where the distinction is important.

It is important to note that although collectivity has a distinct signal, there are possible sources that can produce such a signal which do not involve collective behavior. These sources are called “non-flow” to differentiate them from sources of collectivity, such as flow. Especially true in small collision systems, non-flow is the largest background component when measuring collectivity. Thus, when making measurements, often non-flow must be taken into account as either a systematic uncertainty or as a systematic error correction. Sources of non-flow will be discussed more in Chapter 4 Section 4.5.2.

---

<sup>1</sup> Although it is common to think of collectivity as hydrodynamic behavior, observations of collectivity do not necessarily imply any specific interpretation. Later we will discuss some alternative interpretations such as glasma correlations.

To assist in the discussion of flow, we will briefly describe how it is measured. Generally flow can be observed in heavy ion collisions by looking for long-range angular correlations between the spray of final state particles that come out of the collision. “Long-range angular correlations” in this case refers to correlations in particles with trajectories that have a large separation in pseudorapidity  $\eta$ . When looking for correlations, this separation in  $\eta$  ensures that we are measuring something other than just local correlations, which are often due to non-flow.

Conceptually, the story of flow is that patterns in the initial conditions of the medium will be carried through the medium evolution and be observable in the final state particles. Figure 2.1 demonstrates the key events in the story: initial state geometry becomes transformed into a final state momentum anisotropy. The consideration of initial collision geometry will be a reoccurring theme when interpreting results in this thesis because the initial state geometry is one of the few independent variables over which we have experimental control.

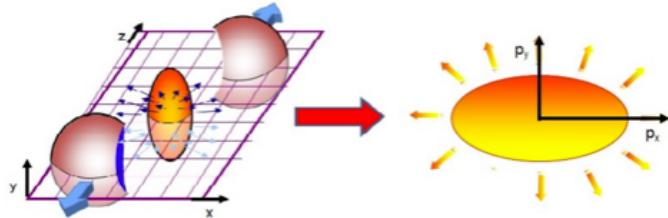

Figure 2.1: A diagram demonstrating the relation between initial state geometry being transformed into final state momentum anisotropy. The left depicts two spherical nuclei colliding parallel to the z-axis. The pair of nuclei leave behind an ellipsoidal shaped medium. This ellipsoid hydrodynamically evolves such that it expands along the steepest pressure gradient which corresponds to the transverse direction. The right depicts the elliptical pattern present in transverse momentum distribution of the final state particles after the medium has finished evolving [26].

### 2.1.1 Initial Conditions

Before proceeding to describing flow mathematically, it is useful to talk about the initial conditions of heavy ion collisions. When talking about collisions of spherically symmetric bodies, one of the most relevant parameters in characterizing collisions is known as the impact parameter.

The impact parameter is the distance between the center of mass of each collision body, the larger the impact parameter, the more peripheral the collision. For heavy ion collisions, it is useful to consider peripheral collisions along with other types, as shown in Figure 2.2. The degree in which the colliding nuclei overlap is known as the “centrality.” A small value for centrality, for example 0-10%, corresponds to more central collision events, while a large value for centrality, for example 60-100%, corresponds to more peripheral collisions. The method for quantifying the event’s centrality is discussed in Chapter 3.

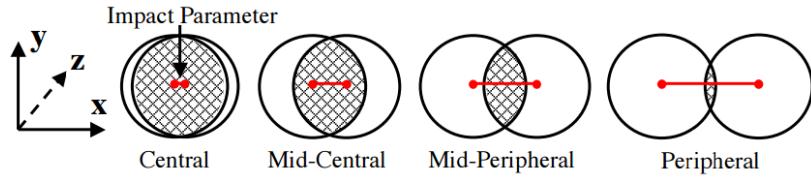

Figure 2.2: A diagram of the possible initial conditions of heavy ion collisions. The impact parameter is the red line. The language used in heavy ion physics is as follows: the larger the overlap between the colliding nuclei, the more central it is, the smaller the overlap, the more peripheral it is. Adapted from [48].

## 2.2 Mathematical Introduction to Measuring and Quantifying Flow

As discussed above, looking for long-range angular correlations is a way to measure flow. Measuring the azimuthal anisotropy is a way to quantify the extent of long-range angular correlation present in the medium evolution. Azimuthal anisotropy is the degree to which measured particles are non-uniform in the transverse plane. There are a number of ways to measure the azimuthal anisotropy. We will start by creating a correlation function.

### 2.2.1 Two-Particle Correlations

A correlation function is dependent on the difference in particles’ trajectories, rather than the trajectories of the particles themselves. Let us consider the two-particle correlation function which uses **pairs** of particles from a collision event in order to create a correlation function. For

each pair in an event, a  $\Delta\phi = \phi_1 - \phi_2$ , and a  $\Delta\eta = \eta_1 - \eta_2$ , value is obtained which makes up the signal  $S(\Delta\phi, \Delta\eta)$  for a single event:

$$S(\Delta\phi, \Delta\eta) = \sum_{j=1}^{N_{\text{particles}}} \left( \sum_{i=j+1}^{N_{\text{particles}}} s(\phi_i - \phi_j, \eta_i - \eta_j) \right) = \sum_{k=1}^{N_{\text{pairs}}} s(\Delta\phi_k, \Delta\eta_k), \quad (2.1)$$

where  $s(\phi_i - \phi_j, \eta_i - \eta_j) = s(\Delta\phi_k, \Delta\eta_k)$  is a single pair in an event,  $N_{\text{particles}}$  is the number of particles in an event, and  $N_{\text{pairs}}$  is the number of unique pairs in an event. This pair counting scheme ensures that no pair will be double counted and that a particle can not form a pair with itself.

Ideally, this  $S(\Delta\phi, \Delta\eta)$  would be the correlation function; however, there are artificial correlations due to detector acceptance and other sources which would distort this distribution. In order to correct for these effects, a mixed event background distribution  $M(\Delta\phi, \Delta\eta)$  is created, whereby pairs are produced by particles from two different events. The correlation function can be defined as follows:

$$C(\Delta\phi, \Delta\eta) = \frac{S(\Delta\phi, \Delta\eta)}{M(\Delta\phi, \Delta\eta)} \frac{\int M(\Delta\phi, \Delta\eta) d\Delta\phi d\Delta\eta}{\int S(\Delta\phi, \Delta\eta) d\Delta\phi d\Delta\eta}, \quad (2.2)$$

where the integration is over the full  $\Delta\phi, \Delta\eta$  range in order to normalize the correlation function. Substantial variations in this  $C(\Delta\phi, p_T)$  are usually seen as long-range angular correlations which can be attributed to collectivity.

In practice, correlation functions often combine particles from two different  $p_T$  ranges. The first  $p_T$  range corresponds to the “trigger” particles and the second range to the “associated” particles. In this scheme, the pair function is  $s(\phi_i^t - \phi_j^a, \eta_i^t - \eta_j^a)$  where the  $t$  superscript indicates trigger particles with a given  $p_T$  range and the  $a$  superscript indicates associated particles with a given  $p_T$  range.

Two examples of 2-D two-particle correlation functions; one for  $p+p$  at  $\sqrt{s_{NN}} = 7$  TeV with no multiplicity selection, and one for Pb+Pb at  $\sqrt{s_{NN}} = 2.76$  TeV high multiplicity events are shown in Figure 2.3. The trigger and associated  $p_T$  ranges are given in the figure caption. Plotting

the correlation function in terms of both  $\Delta\phi$  and  $\Delta\eta$  allows one to see the full extent and location of correlations for the collision system. These two correlations were selected to showcase the two extremes of typical correlation functions.

An important feature in the left plot is the large strength of correlations at  $(\Delta\phi, \Delta\eta) = (0,0)$ , which is known as the nearside<sup>2</sup> “jet peak.” As mentioned in Chapter 1, jets are a spray of particle in a cone shape; therefore, the jet peak is at  $(0,0)$  because all the particles within the jet have a similar trajectory. The jet peak has been truncated for plotting reasons because it is so large. Another important feature is what is known as the “away-side ridge” or “away-side jet peak” located at  $\Delta\phi = \pi$  and extending very far in the  $\Delta\eta$  variable. This feature arises when back-to-back dijets are produced; all of the particles from one of the jets will be roughly  $\pi$  radians apart in trajectory with respect to the other jet and spread out in  $\Delta\eta$ . Apart from these main features which come from jets and dijets, there are no other major sources of correlations between particles for minimum bias  $p+p$  events, such that  $p+p$  events are taken to be the representation of the non-flow background. Minor sources of additional non-flow are in pure decays, Coulomb interactions, and momentum interference. Thus, correlation function features present in regular  $p+p$  events are taken to be present at some level in the correlation function of every heavy ion collision system.

Conversely, the right panel of Figure 2.3 depicts the correlation function of high multiplicity Pb+Pb events which exhibit characteristics of flow. While the non-flow features of the nearside jet peak and the away-side peak are present, a new feature known as the “nearside ridge” is located at  $(\Delta\phi, \Delta\eta) = (0, |\Delta\eta| > \sim 1.0)$ . This ridge exists in contrast to the lack of any correlations in the  $p+p$  correlation function at that location. It should be noted that the away-side jet ridge has also been modified. The nearside ridge and the away-side ridge modification are due to particles with long-range angular correlations. Thus, by quantifying the magnitude of these effects, the degree to which flow is present in the system can be measured.

---

<sup>2</sup> For correlation functions,  $\Delta\phi \sim 0$  is known as “nearside” and  $\Delta\phi \sim \pi$  is known as “away-side.”

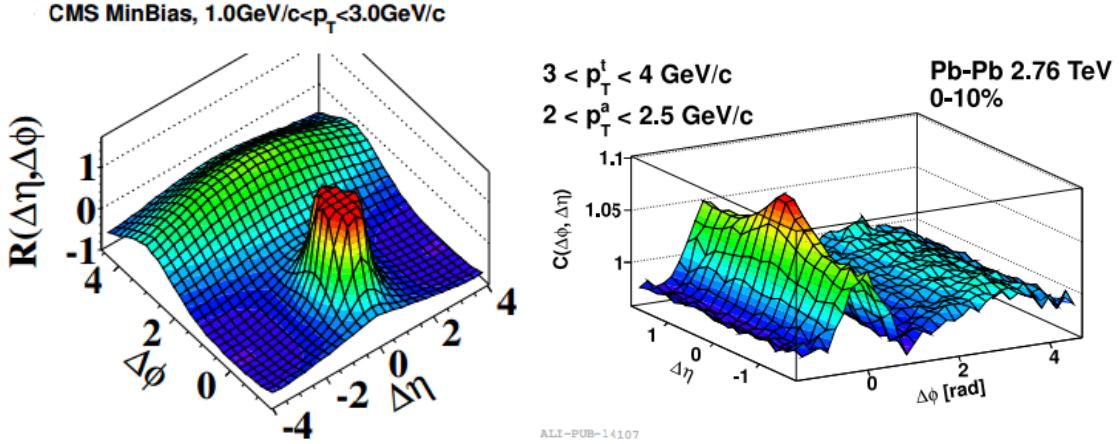

Figure 2.3: The right plot is 2-D two-particle correlation function for  $p+p$  collisions at  $\sqrt{s_{NN}} = 7$  TeV for hadrons with the same trigger and associated  $p_T$  range of  $1.0 < |p_T| < 3.0$  GeV/c for all events [32]. The left plot is 2-D two-particle correlation function for Pb+Pb collisions at  $\sqrt{s_{NN}} = 2.76$  TeV 0-10% centrality events for trigger hadrons with  $3 < p_T^t < 4$  GeV/c and associated hadrons with  $2 < p_T^a < 2.5$  GeV/c measured by ALICE [32].

### 2.2.2 Flow Harmonics

At this point, it is useful to narrow our focus to the region of the correlation function which has long-range angular correlations by taking a projection in  $\Delta\phi$  away from the jet peak at  $\Delta\eta = 0$ . This 1-D two-particle correlation function slice contains the azimuthal anisotropy which should correspond to the degree of flow present in the system. Figure 2.4 depicts this correlation function  $C(\Delta\phi)$  for central Pb+Pb events. In order to quantify the azimuthal anisotropy,  $C(\Delta\phi)$  is cosine Fourier expanded:

$$C(\Delta\phi) \propto 1 + \sum_{n=1} 2v_n \cos(n[\Delta\phi]), \quad (2.3)$$

where  $v_n$  are known as flow coefficients or flow harmonics and  $n$  is the harmonic order [57]. The colored curves in Figure 2.4 are the first five components of the Fourier decomposition and their amplitudes show their relative strength. The green curve, which peaks at  $\Delta\phi = 0$  and  $\pi$ , corresponds to the second order harmonic, which is related to the second order flow coefficient  $v_2$ . The reason  $v_2$  is singled out is because it corresponds to elliptic flow and because it is the observable

measured in this thesis. In order to extract  $v_2$  from this, one must calculate  $c_2$  defined as:

$$c_2^{t,a} = \langle \cos(2(\phi_1^t - \phi_2^a)) \rangle, \quad (2.4)$$

where  $\langle \rangle$  is defined as the average over all events and all particle pairs and where  $\phi_1^t$  and  $\phi_1^a$  is the trigger and associated particles'  $\phi$ , respectively. If the trigger and associated particles sets are the same then  $\sqrt{c_2} = v_2$ ; however, if the trigger and associated particle sets are not the same then  $c_2^{t,a} = v_2^t \times v_2^a$ , where  $v_2^t$  is the  $v_2$  for the set of trigger particles alone and the same with  $v_2^a$ . This ability to resolve  $c_2$  into the two distinct  $v_2$  components is only true if factorization holds, which only occurs when the non-flow component of the measurement is small. This coefficient  $v_2$  directly characterizes the elliptic flow of the number of particles emitted along the direction of the steepest pressure gradient in the initial ellipsoid shown in Figure 2.1.

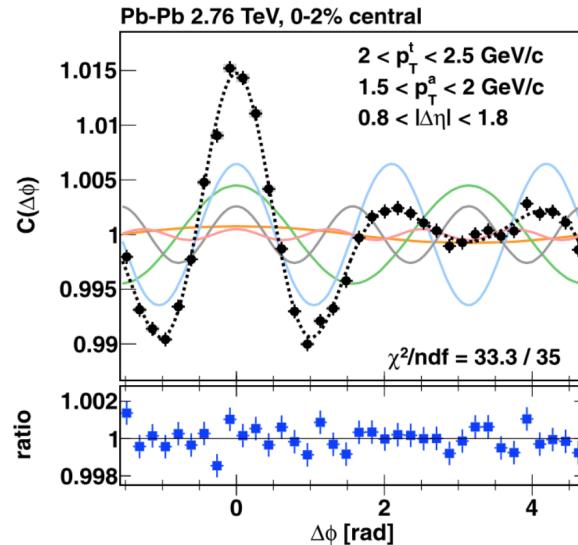

Figure 2.4: The 1-D correlation function in Pb+Pb at  $\sqrt{s_{NN}} = 2.76$  TeV for the most central events for trigger hadrons with  $2 < p_T^t < 2.5$  GeV/c and associated hadrons with  $1.5 < p_T^a < 2$  GeV/c. The 1-D two-particle correlation function is a projection in  $0.8 < |\Delta\eta| < 1.8$  from the 2-D correlation function, the 2-D correlation function being similar to that of the right panel of Figure 2.3. The black dotted points are the values of the correlation function and the colored lines are the first five cos Fourier decomposition components. The black dotted line is the sum of these five components [3].

### 2.2.3 Cumulants

Although two-particle correlations are useful, four-particle correlations or more can be used to better understand the flow measurement. In a multi-particle cumulant treatment,  $c_n\{k\}$  measures the  $n$ th harmonic from groups of  $k$  particles while explicitly subtracting correlations from  $< k$  particles. In this formulation, two-particle cumulants are treated the same way as in two-particle correlation functions:

$$v_2\{2\} = \sqrt{c_2\{2\}} = \sqrt{\langle \cos(2(\phi_1 - \phi_2)) \rangle}, \quad (2.5)$$

whereas four-particle cumulants are defined as:

$$v_2\{4\} = (-c_2\{4\})^{1/4} = (2 \langle \cos(2(\phi_1 - \phi_2)) \rangle)^2 - \langle \cos(2(\phi_1 + \phi_2 - \phi_3 - \phi_4)) \rangle^{1/4}, \quad (2.6)$$

where the term with four  $\phi$  indices corresponds to the four-particle correlation and the term with two  $\phi$  indices corresponds to the subtracted off two-particle correlation term. Multi-particle cumulants are well defined for larger groupings of particles,  $v_2\{6\}$ ,  $v_2\{8\}$ , and up. Comparing  $v_2$  measured by two and four-particle cumulants is useful when estimating the level of fluctuations present in the system, something which will be discussed more in Section 2.4.3.

### 2.2.4 Event Plane Formulation

Another mathematical treatment for determining flow coefficients involves measuring a mathematical object known as an “event plane.” Conceptually, the event plane method is an attempt to measure the reaction plane angle, which defines the plane to which it is aligned with the orientation of the initial state collision geometry. Figure 2.5 is a geometric diagram defining the reaction plane angle  $\Psi_{RP}$ .

The event plane method uses final state particles to calculate the event plane angle from the data. A different event plane angle is defined for each harmonic, and is denoted as  $\Psi_n$  where  $n$  is the harmonic number. For an event with  $N$  particles, define the flow vector  $\vec{Q}$  as follows:

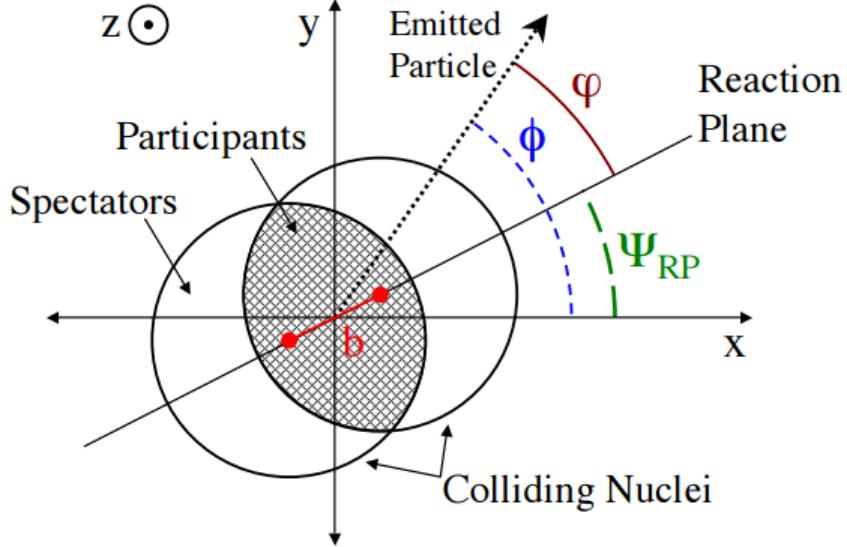

Figure 2.5: Diagram showing from the beams point of view several variables used to characterize events. The spectators are the nucleons which do not participate in the collision, as opposed to the participants which do participate in the collision. The impact parameter denoted as  $b$  and  $\Psi_{RP}$  is the reaction or participant plane angle.  $\phi$  is the standard azimuthal and  $\varphi = \phi - \Psi_{RP}$ . Adapted from [48].

$$Q_x = \sum_i^N (w_i * \cos(n * \phi_i)) \quad (2.7)$$

$$Q_y = \sum_i^N (w_i * \sin(n * \phi_i)) \quad (2.8)$$

$$Q_w = \sum_i^N (w_i) \quad (2.9)$$

where  $i$  is the  $i$ th particle in the event,  $\phi_i$  is the azimuthal angle of the particle,  $w_i$  is the weight factor, and  $n$  is the harmonic number.

We define the  $n$ th order event plane as  $\Psi_n = \arctan\left(\frac{Q_y}{Q_x}\right)$

Once the event plane has been calculated, the flow harmonics ( $v_n$ ) are defined as

$$v_n = \frac{\langle \langle \cos(n(\phi - \Psi_n)) \rangle \rangle}{\text{Resolution}(\Psi_n)}, \quad (2.10)$$

where  $\langle \langle \rangle \rangle$  indicates that  $\cos(2\phi - \psi)$  is averaged over all particles in the same event, and the

resulting  $v_2$  must be averaged over many events [44].

The event plane resolution is calculated using the standard 3-sub event method [44]. The strategy of this method is to measure  $\Psi_n$  with three different detectors in the same event, in order to better constrain the overall measurement of  $\Psi_n$ . The event plane resolution is defined as

$$Res(\Psi_n^A) = \sqrt{\frac{\langle \cos(n(\Psi_n^A - \Psi_n^B)) \rangle \langle \cos(n(\Psi_n^A - \Psi_n^C)) \rangle}{\langle \cos(n(\Psi_n^B - \Psi_n^C)) \rangle}}, \quad (2.11)$$

where A,B, and C are three detectors measuring the same event. In this context, the term “sub-event” refers to the specific subset of particles measured by a given detector [44].

### 2.3 An Overview of Heavy Ion Collectivity Models

Throughout the discovery phase of the Quark Gluon Plasma and beyond into precision measurements, simulations based on theoretical descriptions of heavy ion collisions have been developed and have been successful in describing and predicting physics results. From the initial state of the colliding nuclei to the final state particles produced, every phase of heavy ion collisions are modeled. First the initial condition models will be discussed and then the medium evolution models will be discussed. It is necessary when calculating observables like  $v_n$  to choose an initial state model and a medium evolution model to chain together. The output of the initial state model will be the input to the medium evolution model; therefore, even if the medium evolution model describes the physics well, an initial state model which does not do so would cause the final  $v_n$  calculation to be inconsistent with the data.

#### 2.3.1 Initial Condition Models

Initial condition models use a variety of methods to simulate the colliding nuclei. These models calculate quantities for characterizing initial collision conditions, such as the number of participating nucleons ( $N_{part}$ ), the impact parameter ( $b$ ), and the participant eccentricity ( $\varepsilon$ ). The  $N_{part}$  is the total number of neutrons and protons from the nuclei that suffer at least one inelastic collision, and is thought to be related to the size of the medium produced. The  $\varepsilon_n$  categorizes the

$n$ th order anisotropy in the initial collision geometry which is given by:

$$\varepsilon_n = \frac{\sqrt{<r^2 \cos(n\phi)>^2 + <r^2 \sin(n\phi)>^2}}{<r^2>} \quad (2.12)$$

where  $r$  is the radius of the participant nucleon, relative to the center of mass. This quantity is important because  $v_n \propto \varepsilon_n$  in the limit of ideal hydrodynamics [11].

A key part in simulating initial the conditions of heavy ion collisions is understanding event-to-event fluctuations. An important source of fluctuations, generic to all models of quantum fluctuations, are fluctuations in the distributions of nucleons in the nuclear wavefunctions. In addition, there are fluctuations in the color charge distributions inside a nucleon. This, combined with Lorentz contraction, results in lumpy transverse projections of color charge configurations that vary event to event. There are more sophisticated models where there are simple constituent quark models with the three color charge centers in the nucleon [58]. The scale of this lumpiness is given on average by the nuclear saturation scale  $Q_s$  which corresponds to distance scales smaller than the nucleon size . For each such configuration of color charges, the Quantum Chromo-Dynamics (QCD) parton model predicts dynamical event-by-event fluctuations in the multiplicities, the impact parameters, and the rapidities of produced gluons [51].

### 2.3.1.1 Monte-Carlo Glauber

There are two main Glauber models: the so called “optical” Glauber model which assumes a smooth density described by a Fermi distribution in the radial direction; and the Monte-Carlo-based Glauber model where individual nucleons are stochastically distributed on an event basis and collision properties are determined by averaging over multiple events. The optical form of Glauber does not locate nucleons at specific spatial coordinates like the Monte Carlo form of Glauber. While both models give consistent results for determining simple quantities such as  $\langle N_{part} \rangle$  and  $b$ , the impact parameter, the more statistical Monte-Carlo approach has given  $\varepsilon_n$  values that are necessary for the described experimental data. One benefit of the Monte-Carlo approach for quantities like  $N_{part}$  is its simplicity and ability to simultaneously simulate experimentally observable quantities,

such as charged particle multiplicity distribution.

The Monte-Carlo Glauber (MC Glauber) model calculation is performed in two steps. At first, the nucleon positions in each nucleus are stochastically determined. Then, the two nuclei are collided, assuming the nucleons travel in a straight line along the beam axis (known as the Eikonal approximation), such that nucleons are tagged as wounded (participating) or spectator.

The position of each nucleon in the nucleus is determined according to a probability density function. The probability distribution is typically taken to be uniform in azimuthal and polar angles. The radial probability function is modeled from nuclear charge densities extracted in low-energy electron scattering experiments. The nuclear charge density is usually parameterized by a Fermi distribution with three parameters:

$$\rho(r) = \rho_0 \frac{1 + w(r/R)^2}{1 + \exp(\frac{r-R}{a})} \quad (2.13)$$

where  $\rho_0$  is the nucleon density,  $R$  is the radius of the nucleus,  $a$  is the skin depth, and  $w$  corresponds to deviations from a spherical shape.

The impact parameter of the collision is chosen randomly from a distribution  $dN/db \propto b$  up to some large maximum  $b_{\max}$  with  $b_{\max} \approx 2R_A$ . The longitudinal coordinate does not play a role in the calculation. The inelastic nucleon-nucleon cross section ( $\sigma_{NN}$ ), which is only a function of the collision energy is extracted from p+p collisions. At the top RHIC energy of  $\sqrt{s_{NN}} = 200$  GeV,  $\sigma_{NN} = 42$  mb, while at the LHC it is expected to be around  $\sigma_{NN} = 72$  mb [38]. The ball diameter is defined as:

$$D = \sqrt{\frac{\sigma_{NN}}{\pi}}. \quad (2.14)$$

Two nucleons from different nuclei are assumed to collide if their relative transverse distance is less than the ball diameter. If no such nucleon-nucleon collision is registered for any pair of nucleons, then no nucleus-nucleus collision occurred. An example Au+Au collision event is shown in Figure 2.6. In this thesis, MC-Glauber combined with negative binomial distributions is used to match the charged particle multiplicity distribution in order to map  $N_{part}$  to centrality classes. Details

for this procedure are given in Chapter 3, Section xxx.

As stated earlier, an important initial condition quantity in simulating flow is the  $\varepsilon$  of the event. MC Glauber simply calculates the moments of the participants themselves for each event. The eccentricity  $\varepsilon_2$  can be calculated along the axis of the participant distribution  $\varepsilon_{part}$ :

$$\varepsilon_{part} = \frac{\sqrt{(\sigma_x^2 - \sigma_y^2)^2 + 4(\sigma_{xy})^2}}{\sigma_x^2 - \sigma_y^2} \quad (2.15)$$

where  $\sigma_{x,y}^2$  are the  $x$  and  $y$  variances for participating nucleons and  $\sigma_{xy}$  is the covariance of  $x$  and  $y$  for participating nucleons.

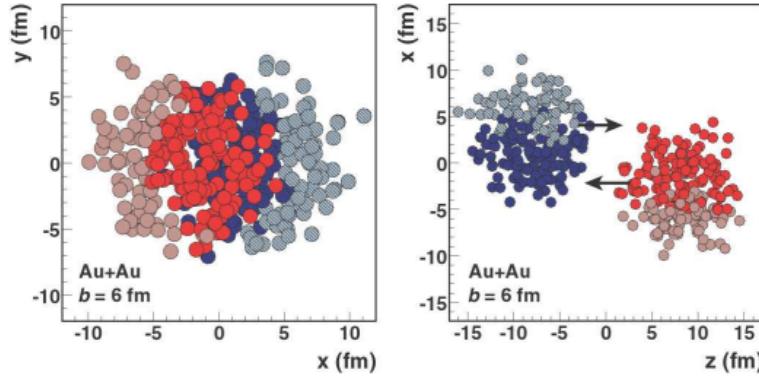

Figure 2.6: Glauber Monte Carlo event (Au+Au  $\sqrt{s_{NN}} = 200$  GeV with impact parameter  $b = 6$  fm) viewed in the transverse panel and along the beam axis in the left and right panels, respectively. The deeper color disks correspond to the participating nucleons [38].

### 2.3.1.2 IP-Glasma

Another initial state model is known as IP-Glasma. This model calculates the initial conditions within a Color Glass Condensate (CGC) framework by combining the impact parameter dependent saturation model (IP-Sat) with the Classical Yang-Mills (CYM) description of initial Glasma fields. Calculating initial state dynamics by flowing Glasma gluon fields is thought to be an *ab initio*, or from first principles, approach, although some of the parameters of the model are fixed by diffractive e+p DIS data. The IP-Glasma computation starts by sampling the positions of the constituent nucleons from a Fermi distribution. Then the saturation scale  $Q_{s,(p)}^2(x, \mathbf{b})$  is obtained

from IP-Sat dipole cross section for each nucleus, where  $b$  is the impact parameter relative to each participant nucleon's center. Once the saturation scale and the color charge density are obtained, random color charges are sampled from a transverse lattice [51].

A benefit of the IP-Glasma model is that it explicitly includes multiple types of quantum fluctuations, including fluctuations of color charges within the nucleons. It is useful to compare the calculations of IP-Glasma to MC-Glauber in order to gain a greater understanding of both.

### 2.3.1.3 Comparison between IP-Glasma and MC-Glauber

Figure 2.7 depicts the energy density distributions calculated by the IP-Glasma and MC-Glauber models. It is apparent from the “lumpiness” of both of these distribution that these models capture the complex internal structure of the nuclei at the moment of collision. However, the MC-Glauber distribution is much smoother than the IP-Glasma distribution due to the fact that the IP-Glasma distribution incorporates fluctuations at a much finer length-scale, given by  $1/Q_s(x)$ , which creates the spiky structures in the energy distribution. Apart from the differences in the length-scale of fluctuations between the models, MC-Glauber includes the energy distribution from every participant nucleon in the collision event, no matter how glancing its individual collision is, with the same parameters of width. Thus, the MC-Glauber model’s procedure for incorporating participating nucleons is less sophisticated than a model like IP-Glasma. Note that for MC-Glauber, the width of a nucleon’s energy density has been chosen to be 0.4 fm for all nucleons to match the MC-Glauber model to the data, despite the fact there are no *ab initio* calculations which derive such a number.

### 2.3.2 Medium Evolution Models

Once an energy density distribution is calculated from the initial condition models, it used as the input to a medium evolution model. The most commonly used medium evolution model is the relativistic hydrodynamic model.

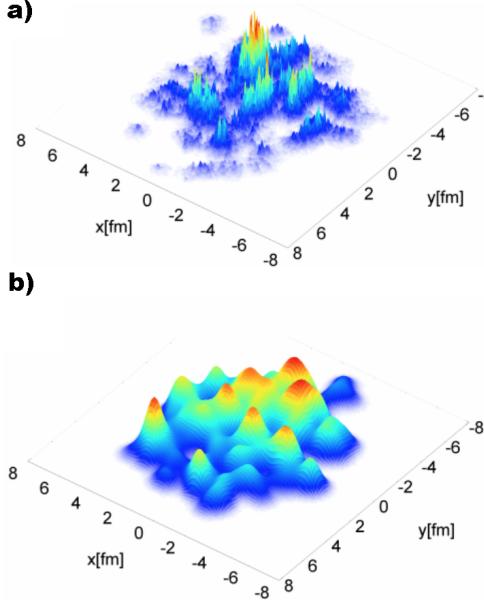

Figure 2.7: Initial energy density distributions (arbitrary units) in the transverse plane in two different heavy-ion collision events for IP-glasma (top) MC-Glauber (bottom) models [51].

### 2.3.2.1 Hydrodynamic Modeling

Relativistic hydrodynamics is a macroscopic tool to simulate the evolution of a strongly coupled QGP medium. It is based on the foundational physical principles of conservation of energy, momentum, and net charge current which are written as:

$$\delta_\mu T^{\mu\nu}(x) = 0, \quad (2.16)$$

$$\delta_\mu N^\mu(x) = 0, \quad (2.17)$$

where  $T^{\mu\nu}$  is the energy momentum tensor and  $N^\mu$  is the net baryon charge current. Ideal hydrodynamics requires that the medium is locally equilibrated, such that we have the perfect fluid energy momentum tensor as  $T^{\mu\nu} = (e+p)u^\mu u^\nu + pg^{\mu\nu}$  where  $e$  is the relativistic rest energy density,  $p$  is the fluid pressure,  $g^{\mu\nu}$  is the Minkowski metric, and  $u^\mu$  is the four-velocity of fluid. Also, the charge current becomes  $N^\mu = n u^\mu$  where  $n_0$  is the net baryon density. After asserting an equation of state (EoS)  $p = p(n_0, e)$ , the system is closed and the equations can be solved numerically.

Viscous hydrodynamics is similar to ideal hydrodynamics except that viscous hydrodynamics applies to a wider variety of systems, such as imperfectly locally equilibrated systems. In order to account for the lack of equilibrium, several new variables must be introduced:  $\pi^{\mu\nu}$  is the sheer stress tensor,  $\Pi$  is the bulk pressure,  $\eta$  is the shear viscosity,  $\zeta$  is the bulk viscosity,  $V^\mu$  is the baryon flow, and  $\tau_\pi$  and  $\tau_\Pi$  are the corresponding relaxation times. At RHIC and LHC energies, the net baryon density  $n_0$  is nearly zero and  $v^\mu$  is assumed to be zero. By choosing a proper EoS (equation of state), an initial flow velocity, and an initial entropy/energy density at time  $\tau_0$ , the medium evolution can be simulated for time  $\tau > \tau_0$ . Note that in order to simulate very early stages during the QGP formation, modifications to this hydrodynamic formulation must account for pre-equilibrium conditions [54]. An example of a viscous hydrodynamic evolution is shown in Figure 2.8 for a collision of  ${}^3\text{He}+\text{Au}$ .

To obtain final state hadrons, pure hydrodynamic simulations assume free hadron resonances directly emit from the fluid along a decoupling surface. The Cooper-Frye formula [18] is then implemented to calculate the particle momentum distributions, which is followed by a resonance decay routine to generate final stable hadrons. The decoupling or freeze out surface can be defined by a constant temperature or energy density or other kinetic variables. For the scenario of constant temperature decoupling,  $T_{dec}$  is generally set to 150-170 MeV, depending on the EoS and other hydrodynamic inputs, to allow for sufficient evolution time to build up enough radial flow to fit the slopes of the  $p_T$  spectra [33].

To simplify numerical simulations, many viscous hydrodynamic calculations assume a specific velocity profile  $v_z = z/t$  along the beam directions (Bjorken approximation). This approximation leads to a longitudinal boost invariance and reduces the (3+1)-d hydrodynamics to (2+1)-d hydrodynamics. This approximation has shown that the realistic longitudinal expansion only slightly affects the flow profiles at mid-rapidity [54].

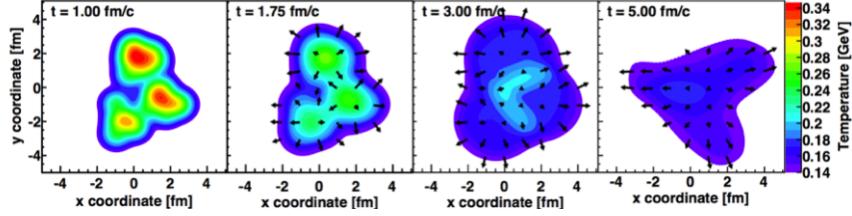

Figure 2.8: An example time evolution of a  ${}^3\text{He} + \text{Au}$  event from the initial state to final state. The color scale indicates the local temperature and the arrows are proportional to the velocity of the fluid cell from which the arrow originates [40].

### 2.3.2.2 Hybrid Models: SONIC and superSONIC

Here we detail one specific model, noting that many viable hydrodynamic models have been developed [15]. A hybrid model matches hydrodynamic descriptions of the expanding QGP to microscopic Boltzmann simulations of the evolving hadronic matter. The transition between models is realized by a Monte-Carlo event generator, which transforms the hydrodynamic output into individual hadrons for succeeding hadron cascade propagations.

The “Super hybrid mOdel simulatioN for relativistic heavy-Ion Collisions” (SONIC) combines pre-equilibrium dynamics with hydrodynamics [36] and a late-stage hadronic cascade [39]. In effect, SONIC has only a limited number of parameters, namely those specifying the properties of the incoming nuclei, equation of states as input to from lattice QCD, and shear and bulk viscosities in the QGP. As discussed when describing initial conditions models, fluctuations play a large role in determining the hydrodynamic flow. In order to study the effects of fluctuations in simulation, SONIC is an event-by-event simulation is created by inputting fluctuating initial conditions, evolving each system separately, and then averaging the results.

SuperSONIC is the next generation of the SONIC model, differing from SONIC by incorporating pre-equilibrium dynamics with a calculation in the framework of the AdS/CFT correspondence [49]. The SONIC and superSONIC models agree well with the data within uncertainties.

### 2.3.3 AMPT

A Multi-Phase Transport (AMPT) model combines partonic and hadronic scattering in a single model. AMPT is the culmination of many models together. It is in an alternative to the hydrodynamic approach of medium evolution by using partonic strings instead of fluid cells as the building blocks of the model. The use of partonic strings preserve discrete particle information throughout the simulation which is useful in dissecting simulations. Despite the fact that AMPT is not a hydrodynamic model, it still is consistent with substantial flow coefficients as will be shown in Chapter 5.

AMPT consists of four main components: the initial conditions, partonic interactions, the conversion from the partonic to the hadronic matter, and hadronic interactions. AMPT uses the Heavy Ion Jet Interaction Generator (HIJING) for generating the initial conditions, Zhang's Parton Cascade (ZPC) for modeling partonic scatterings, the Lund string fragmentation model or a quark coalescence model for hadronization, and A Relativistic Transport (ART) model for treating hadronic scatterings. The HIJING model converts the initial incident energy to the production of hard minijet partons and soft strings, with excited strings further converting to partons in the AMPT model with string melting. Then ZPC is used to model the interactions among partons. An implementation of the Lund string fragmentation converts the excited strings to hadrons. The ART model is used for describing interactions among hadrons [35].

## 2.4 A Review of Flow Measurements in Small Collision Systems

As noted at the end of Chapter 1, small collision systems have long been considered too small to create hot and dense matter. These systems were utilized as control experiments which measure how the presence of a nucleus would effect the production of particles relative to  $p+p$  collisions. These so called "cold nuclear matter" (CNM) effects were isolated when colliding very low  $Z$  nuclei, such as a deuteron or proton, with a large nucleus.<sup>3</sup> Generally accepted CNM effects are:

---

<sup>3</sup> A side note: the convention in the field of heavy ion physics is to label any such small system collisions as  $p+A$  and any large system collisions as  $A+A$

nuclear shadowing, which is the modification of parton distribution functions by a nucleus; gluon saturation, which is the saturation of gluon distribution functions where no gluons can be added; radiative energy loss, which is the modification of the momentum fraction of partons due to multiple soft scatterings; and finally the Cronin effect, which is the broadening of the transverse momentum of emitted particles distribution due to multiple scatterings of initially colliding partons [25].

#### 2.4.1 Nearside Ridge in Small Systems

In 2010, the CMS collaboration published a paper observing a nearside ridge in high multiplicity 7 TeV  $p+p$  events in the two-particle correlation function for dihadrons as shown in the left Figure 2.9. The aforementioned nearside ridge is located at  $\Delta\phi = 0$  and at  $|\Delta\eta| > 2$  in the figure. The ridge is significant in contrast to the  $p+p$  correlation function shown in the right panel of Figure 2.9 with an absence of any such ridge.

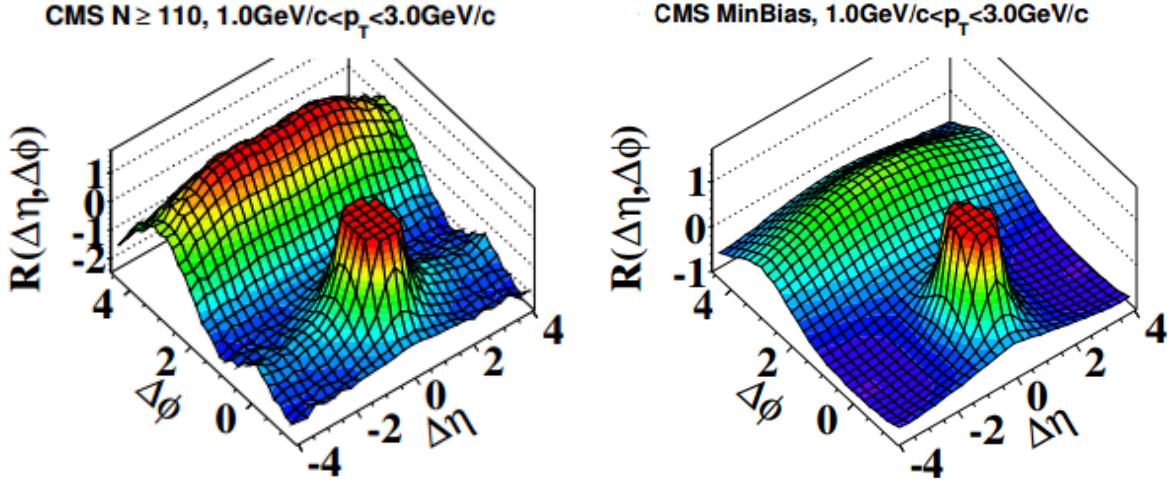

Figure 2.9: 2-D two-particle correlation function for  $p+p$  collisions at  $\sqrt{s_{NN}} = 7$  TeV for hadrons with  $1.0 < |p_T| < 3.0$  GeV/c in high multiplicity events, with greater than 109 charged particles, and for any multiplicity of events are shown in the left and right panels, respectively [32].

What this discovery showed was that collectivity-like effects could be measured in small collisions systems for high-multiplicity events. Thus,  $p+\text{Pb}$  at  $\sqrt{s_{NN}} = 5.02$  TeV events were also analyzed to find flow and a nearside ridge was observed in 0-20% central events. It became apparent

over the course of making these measurements that the non-flow contribution to the signal would be much larger for p+p and p+A events than that of A+A events and so perhaps these were not related to flow. However, a procedure to reduce the non-flow component in the flow measurement is demonstrated in Figure 2.10. The procedure measures the same two-particle correlation function for central and peripheral events, in this case 0-20% central and 60-100% central and then subtracts the central correlation function by the peripheral one. The assumption is that the level and shape of the non-flow is mostly consistent across centrality classes, whereas the flow is centrality dependent, such that there is virtually no flow in the peripheral correlation function. Thus, by subtracting the central correlation function by the peripheral, only the common components to both will be subtracted out, which are the non-flow components. As seen in panel three in Figure 2.10, the subtracted correlation function has no dominating jet peak at (0,0) and the nearside and away-side ridges are distinct and clear, with a signal dominated by elliptic flow.

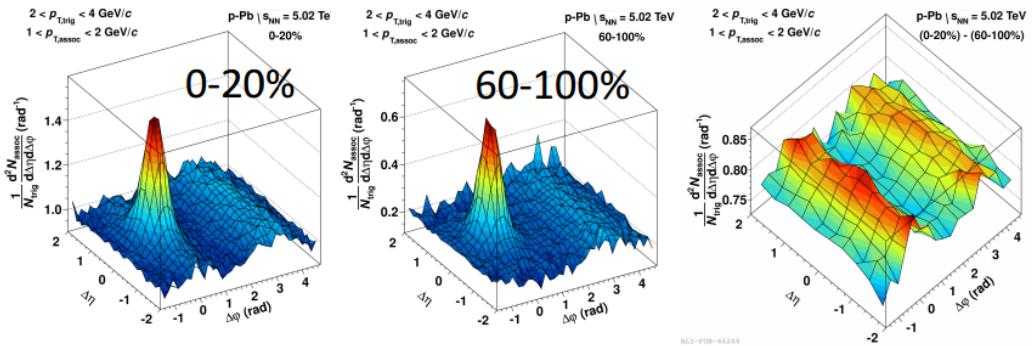

Figure 2.10: 2-D two-particle dihadron correlation function for  $p+Pb$  collisions for 0-20% and 60-100% centrality events as measured by the ALICE detector in the left and middle panel, respectively. The rightmost panel shows the subtraction of the left panel by the middle panel to remove background. [?]

#### 2.4.2 Mass Ordering in $v_2$

A key observation in the determination of real collective flow is a mass ordering in the strength of the flow coefficients. This is due to a common velocity field in the fluid which then results in

a larger momentum boost for heavier particles. The left panel of Figure 2.11 depicts the observed mass ordering of particles in Pb+Pb 10-20% centrality events. In the low  $p_T$  region of 0 - 2 GeV, there is an ordering in the magnitude of  $v_2$  for hadrons:  $\pi^\pm > K^\pm > p+\bar{p}$  and so on for other heavier particles. The  $\pi^\pm$   $v_2$  is the largest while the  $\pi^\pm$  mass is the smallest. Assuming an elliptic flow is present, the steep pressure gradients will efficiently modify the magnitude of  $p_T$  for heavy hadrons more than for light hadrons, leading to a reduction in the number of heavy hadrons available at low  $p_T$  to produce a low  $p_T$   $v_2$  [30]. Thus, the mass ordering observation is taken to be evidence that the system is creating a medium such that particles will flow in predictable ways.

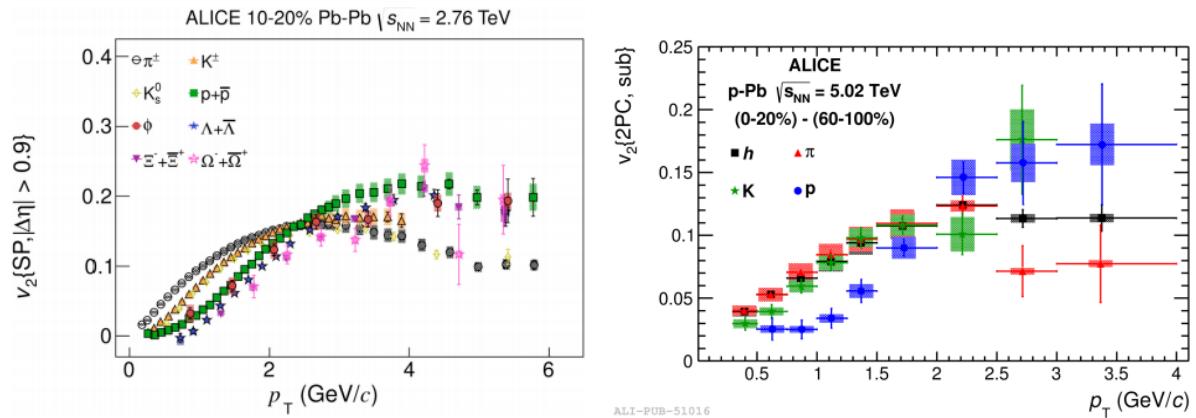

Figure 2.11:  $v_2(p_T)$  for different particles (see legend) in Pb-Pb  $\sqrt{s_{NN}} = 2.76$  TeV 10-20% events as measured by the ALICE detector. The  $\Delta\eta$  gap at minimum is 0.9 units. The right plot shows the  $v_2(p_T)$  for different particles (see legend) in p-Pb  $\sqrt{s_{NN}} = 5.02$  TeV for 0-20% events that were subtracted by peripheral 60-100% events. The  $v_2$  is extracted directly from the two particle correlation function shown in Figure 2.10. [add refs](#)

The right panel of Figure 2.11 shows a similar plot to the left panel of that figure except for the system  $p+\text{Pb}$   $\sqrt{s_{NN}} = 5.02$  TeV. As in the Pb+Pb system, the  $p+\text{Pb}$  dataset exhibits the same mass ordering, as well as similar shapes of each  $v_2(p_T)$  curve. Thus, the mass ordering effect that is observed in A+A is also observed in small systems, such as p+A. An important note for the result on the right panel is that a central minus peripheral subtraction was done, as demonstrated in Figure 2.10, whereas the result in the left panel needed no such peripheral subtraction. This means it is difficult to compare directly with the A+A result in magnitude, although the similarity

of the ordering and the shape of the curves is enough of a comparison to indicate collectivity in the small system.

#### 2.4.3 Multi-Particle Cumulants and Fluctuations

The effects of event-to-event fluctuations in the elliptic flow measurement have been studied in small systems. In this context, fluctuations are differences in the initial collision geometry  $\varepsilon_2$  from one event to the next and so  $v_2$  is different from one event to the next. Fluctuations in  $\varepsilon_2$  can arise from fluctuations in the impact parameter within a centrality class of events and from fluctuations of the initial positions of the participant nucleons [41].

In order to better understand the effect of fluctuations in our small systems measurements,  $v_2$  was measured in different ways such as,  $v_2\{2\}$  and  $v_2\{4\}$ , which are given by Equations 2.5 and 2.6, respectively. The quantity  $v_2\{2\}$  is the same as the two-particle correlation  $v_2$ , shown in Figure 2.11, while the quantity  $v_2\{4\}$  is a four-particle correlation. This paper referenced here [41], defines a fluctuation term similar in form to standard deviation that is related to flow coefficients defined:

$$\sigma_\nu^2 \equiv \langle \nu^2 \rangle - \langle \nu \rangle^2, \quad (2.18)$$

where  $\nu$  is the flow coefficient relative to the participant plane. This fluctuation term is related to  $v_2\{2\}$  and  $v_2\{4\}$  as

$$\nu\{2\}^2 = \langle \nu^2 \rangle = \langle \nu \rangle^2 + \sigma_\nu^2, \quad (2.19)$$

and

$$\nu\{4\}^2 = (2 \langle \nu^2 \rangle^2 - \langle \nu^4 \rangle)^{1/2} \approx \langle \nu \rangle^2 - \sigma_\nu^2. \quad (2.20)$$

Thus,  $v_2\{2\}$  measures the true elliptical flow plus fluctuations, whereas  $v_2\{4\}$  measures the true elliptical flow minus fluctuations. By measuring both  $v_2\{2\}$  and  $v_2\{4\}$  for the same dataset, an estimate of the size of the fluctuations can be obtained. The difference between the two and four particle cumulants should be  $\approx$  twice the size of the fluctuations.

Figure 2.12 shows the measurement of multi-particle cumulants in  $p+p$ ,  $p+\text{Pb}$ , and  $\text{Pb}+\text{Pb}$  by the CMS collaboration at the LHC. A key part of this plot is noticing the significant difference between  $v_2\{2\}$  and  $v_2\{4\}$  in high multiplicity  $p+\text{Pb}$  and  $\text{Pb}+\text{Pb}$  events, indicating the presence expected geometry and thus flow fluctuations. In the  $p+\text{Pb}$  and  $\text{Pb}+\text{Pb}$  there is an apparent multiplicity threshold, approximately around  $N_{\text{trk}}^{\text{offline}} = 75$ , below which a class of peripheral events have a different kind of behavior than the high multiplicity events.

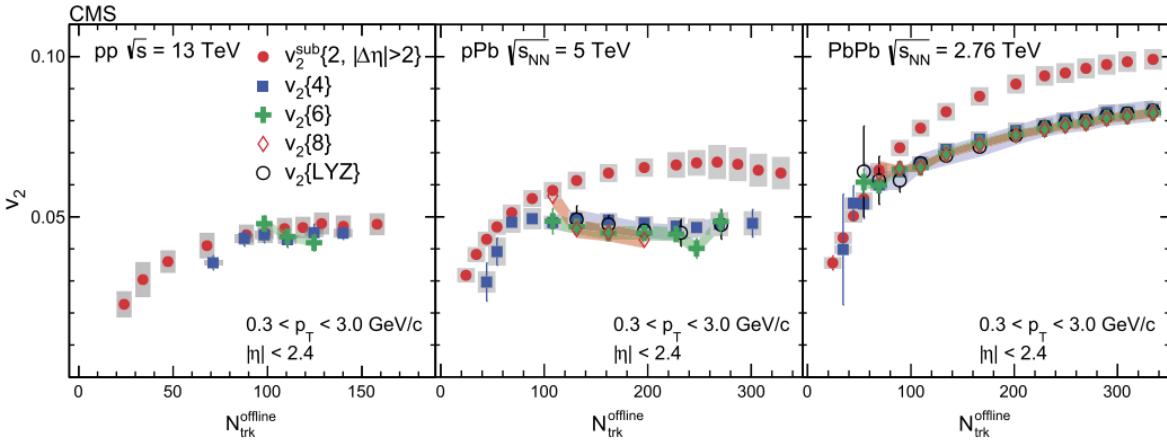

Figure 2.12: Elliptic flow measurements made using the 2nd, 4th, 6th, and 8th multi-particle cumulants, where the 2nd multi-particle is subtracted by peripheral events. Also the Lee Yang zero method non-flow elimination method is shown. These quantities are plotted vs the event multiplicity measured as  $N_{\text{trk}}^{\text{offline}}$ , which is the number of charged particle tracks observed during the offline analysis averaged over  $0.3 < p_T < 3.0 \text{ GeV}/c$  and over  $|\eta| < 2.4$ . The left panel is  $v_2^{\text{sub}}\{2, |\Delta\eta| > 2\}$ ,  $v_2\{4\}$ , and  $v_2\{6\}$  in  $p+p$  collisions at  $\sqrt{s} = 13 \text{ TeV}$ . The middle panel  $v_2^{\text{sub}}\{2, |\Delta\eta| > 2\}$ ,  $v_2\{4\}$ ,  $v_2\{6\}$ ,  $v_2\{8\}$ , and  $v_2\{\text{LYZ}\}$  in  $p+\text{Pb}$  at  $\sqrt{s_{\text{NN}}} = 5 \text{ TeV}$  collisions. The right panel is  $v_2^{\text{sub}}\{2, |\Delta\eta| > 2\}$ ,  $v_2\{4\}$ ,  $v_2\{6\}$ ,  $v_2\{8\}$ , and  $v_2\{\text{LYZ}\}$  in  $\text{Pb}+\text{Pb}$  collisions at  $\sqrt{s_{\text{NN}}} = 2.76 \text{ TeV}$ . The error bars correspond to the statistical uncertainties, while the shaded regions correspond to the systematic uncertainties [31].

It is also interesting to note that for both systems, the  $v_2\{4\}$ ,  $v_2\{6\}$ ,  $v_2\{8\}$ ,  $v_2\{\text{LYZ}\}$  are in excellent agreement. The  $v_2\{\text{LYZ}\}$  is  $v_2$  measured taking into account the Lee-Yang zeros by removing all lower-order correlations. This excellent agreement indicates that  $p+\text{Pb}$  is similar to  $\text{Pb}+\text{Pb}$  in that it is an N-body correlation, not a two-body decay or back-to-back jets which produces correlations between smaller numbers of particles. Although these types of processes are

present, all particles feel the effects of the initial geometry.

#### 2.4.4 Measurements Made at RHIC

Flow measurements in small systems have also been made at the lower energy accelerator, RHIC. Small collision systems,  $d+\text{Au}$ ,  ${}^3\text{He}+\text{Au}$ , and  $p+\text{Au}$  at  $\sqrt{s_{NN}} = 200$  GeV per nucleon were taken at RHIC in 2008, 2014, and 2015, respectively. The 2008  $d+\text{Au}$  dataset was intended to measure cold nuclear matter effects; however, RHIC experiments such as PHENIX had the capability to go back and measure  $v_2(p_T)$ . PHENIX was able to measure  $v_2$  for  $d+\text{Au}$  and for  ${}^3\text{He}+\text{Au}$  for the 0-5% most central events, as shown in Figure 2.13. A substantial  $v_2$  is observed for both  $d+\text{Au}$  and  ${}^3\text{He}+\text{Au}$  events with a strong  $p_T$  dependence, which is similar to that seen in  $p+\text{Pb}$  at the LHC. Instead of subtracting the non-flow component, as was done in Figure 2.10, the non-flow is incorporated as a systematic uncertainty. In addition to the  $v_2$  measurement, a substantial  $v_3$  is measured for the  ${}^3\text{He}+\text{Au}$  dataset. This measurement is significant because the observation of more than one flow indicates the system is exhibiting complex behavior. A single flow harmonic could be explained by a variety of causes, whereas two flow harmonics from the same system narrow the range of possible explanations.

In addition to measuring the  $v_2(p_T)$  for all hadrons,  $v_2$  has been measured for  $\pi^\pm$  and  $p+\bar{p}$ , as seen in Figure 2.14. A very similar mass ordering in  $v_2(p_T)$  for different hadrons that was observed for  $p+\text{Pb}$  at  $\sqrt{s_{NN}} = 5.02$  TeV in Figure 2.11, was also observed for  $d+\text{Au}$  and  ${}^3\text{He}+\text{Au}$  at  $\sqrt{s_{NN}} = 200$  GeV. In the low  $p_T$  region,  $p_T < 1.5$  GeV, the  $v_2$  for  $\pi^\pm$  is greater than the  $v_2$  for  $p+\bar{p}$ . An interesting note here is that the low  $p_T$  region only goes up to 1.5 GeV/c, whereas the  $p+\text{Pb}$  dataset shows a low  $p_T$  mass ordering region of up to 2 GeV/c. The reason for this is probably due to the difference in center of mass energy, and larger radial flow at the higher energy.

It is necessary to note that throughout all of these measurements in small systems, a skepticism to the interpretation that the measurements are hydrodynamic flow has persisted. There are alternative explanations to the apparent flow measured in small systems which do not involve the creation of a medium. Examples of these alternative examples include:

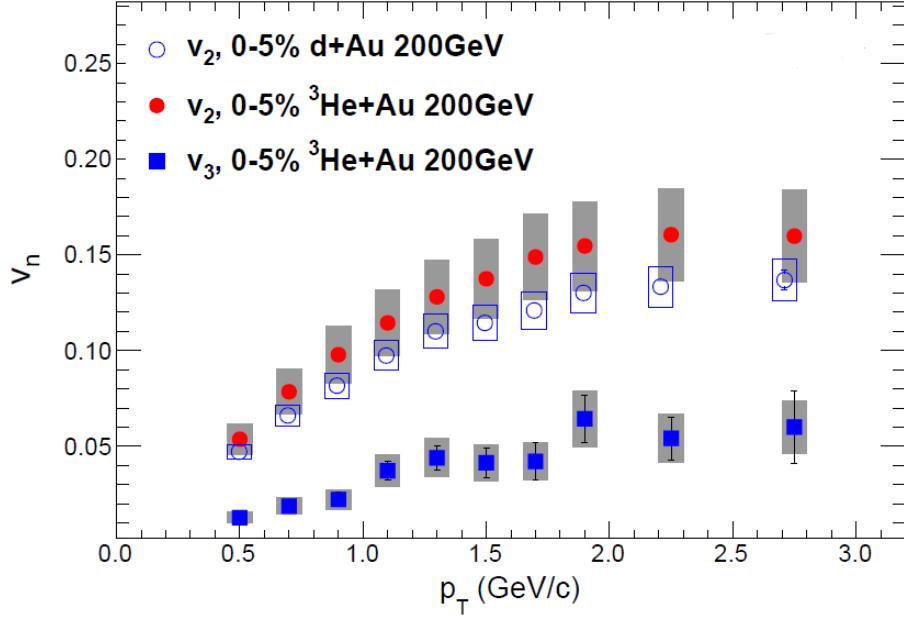

Figure 2.13:  $v_n(p_T)$  measured for  $d+\text{Au}$  and  $^3\text{He}+\text{Au}$  at  $\sqrt{s_{NN}} = 200$  GeV for 0-5% central events.  $v_2$  was measured for both systems and  $v_3$  was measured for  $^3\text{He}+\text{Au}$ . The grey boxes correspond to systematic uncertainties [7].

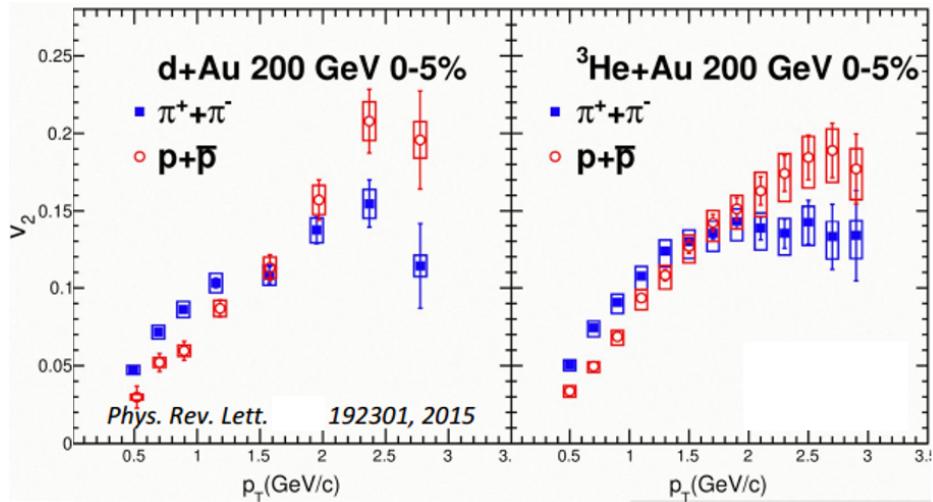

Figure 2.14:  $v_2(p_T)$  for  $d+\text{Au}$  and  $^3\text{He}+\text{Au}$  at  $\sqrt{s_{NN}} = 200$  GeV 0-5% centrality events for  $\pi^\pm$  and  $p+\bar{p}$  separately. The boxes correspond to the systematic uncertainty [7].

initial state effects from plasma diagrams [19], color recombination [43], and partonic scattering in transport models [16]. In order to further the discussion on the distinction between a medium

and a non-medium explanation, three different small collision systems, each with unique initial conditions, were run at RHIC. Those three systems are  $d+\text{Au}$ ,  ${}^3\text{He}+\text{Au}$ , and finally  $p+\text{Au}$ , with intrinsic elliptical, triangular, and circular geometric initial conditions. The constraints that a set of measurements from all three systems would place upon explanatory models would help distinguish which theory best describes small systems. This thesis is the completion of that set of three measurements, by measuring  $v_2$  in the  $p+\text{Au}$  dataset.

## Chapter 3

### Experiment Setup

#### 3.1 RHIC

The Relativistic Heavy Ion Collider (RHIC) is a superconducting charged hadron collider located at Brookhaven National Labs (BNL) in Upton, NY, United States. RHIC is capable of accelerating heavy ions such as Au (gold) or Cu (copper) nuclei to energies of  $\sim 100$  GeV per nucleon. RHIC is also capable of accelerating lighter ions such as protons, deuteron, and helium to  $\sim 100$  GeV per nucleon and  $\sim 250$  GeV per proton, in the case of  $p+p$ . The machine has been demonstrated the ability to reliably create the so called QGP (Quark Gluon Plasma) matter.

There are two major detector experiments currently operating in interaction regions around the RHIC ring: PHENIX (Pioneering High Energy Nuclear Interaction eXperiment) and STAR (Solenoidal Tracker at RHIC). Figure 3.1 shows the locations of the experiments and the accelerator chain. A typical schedule for RHIC is to operate the accelerator for five and a half months every year in what is called a “Run.” There have been 16 Runs so far but the relevant Run for this thesis was the 15th Run taken in 2015 which ran proton colliding with gold ions ( $p+\text{Au}$ )  $\sqrt{s_{NN}} = 200$  GeV for part of its running. Specific details about this dataset are found in section 3.2.9.

RHIC is at the end of a chain of smaller accelerators that are used to ”feed” the ions into RHIC, where they are accelerated (or decelerated in some circumstances) to the desired collision energy. For heavy ions such as Au, the process is listed in detail below [50].

- (1) A pulsed sputter Au ion source generates negative ions in the Tandem Van De Graaff.

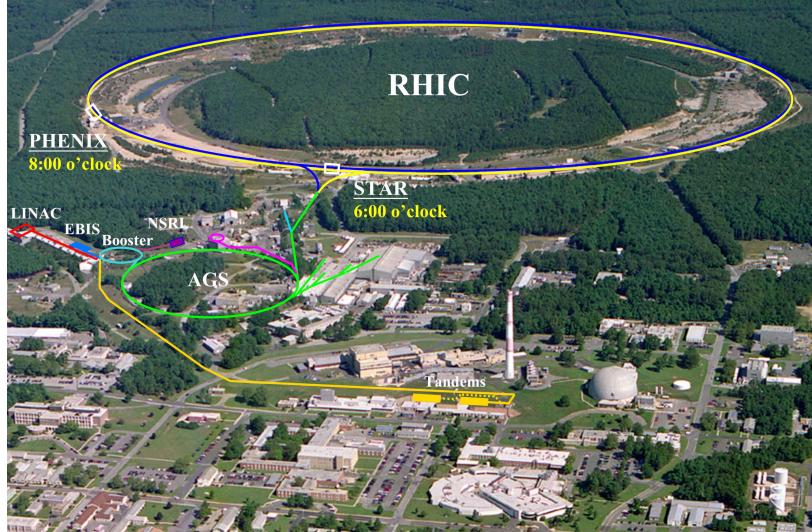

Figure 3.1: A helicopter's view of the accelerator chain in BNL starting at the Tandems (in gold) and ending at the RHIC ring (in blue). STAR and PHENIX can be seen at two of the interaction regions. The ring is 2.38 miles in circumference [55].

- (2) The ions are passed through an electron stripping foil to achieve a positive 12 charge and accelerated to  $\sim 1$  MeV per nucleon.
- (3) The ions pass through bending magnets and another foil to further strip electrons and filter charge, yielding to a positive 32 charge state.
- (4) The ions are sent to the Booster Synchrotron, which accelerates them to 95 MeV per nucleon and leaves them at a positive 77 charge.
- (5) The ions enter the Alternating Gradient Synchrotron (AGS) in bunches of 24 ions. The ions are debunched and rebunched into four bunches and then accelerated to 10.8 GeV per nucleon.
- (6) The bunches then exit the AGS one at a time, where their Au ions are stripped of their two remaining electrons, yielding a final charge state of positive 79. Finally, the bunches are transferred to their respective buckets in RHIC .

For protons, the process instead begins at the the Linear Accelerator (LINAC) facility. The

protons are then sent through the chain of accelerators in a similar way to the heavy ions until reaching RHIC in either a polarized or unpolarized state.

Once the ions have reached RHIC, they will enter one of two independent rings, blue or yellow, each circulating in an opposite direction. The ions in the rings are deflected and focused by 1,740 superconducting magnets using niobium-titanium conductors. Once the ions are focused and accelerated to the desired parameters around the RHIC, the ions are deflected into the six interaction regions where the blue and yellow rings intersect to produce collisions. It is at these interaction regions where the major experiments have set up their detectors, with STAR at the 6 o'clock position and PHENIX at the 8 o'clock position.

The period of time that collisions continue is known as a “fill,” and the average length of a fill is eight hours. As the fill wears on, the collision rate substantially decreases as the density of ions in the machine decreases. Once the collision rate has been reduced sufficiently, it is more cost efficient to start the fill over at a higher collision rate.

### **3.2 PHENIX**

PHENIX, the Pioneering High Energy Nuclear Interaction eXperiment, came online in 2000 along with RHIC and is located at the 8 o'clock interaction region along the RHIC ring. PHENIX is one of the two major RHIC experiments along with STAR, the Solenoidal Tracker At RHIC. The PHENIX detector philosophy differs from STAR in that PHENIX has a small acceptance but very good PID (particle identification) capabilities.

PHENIX’s detectors throughout the years include (in no particular order) the Drift Chamber (DC), the Pad Chambers (PC), the Ring Imaging Cherenkov (RICH) Detector, the Hadron Blind Detector (HBD), the Time Expansion Chamber (TEC), the Time of Flight (TOF), the Electromagnetic Calorimeter (EMCAL), the Muon Tracker (MuTr), the Muon Identifier (MuID), the Muon Piston Calorimeter (MPC), the Muon Piston Calorimeter Extension (MPC-EX), the Beam-Beam Counter (BBC), the Zero Degree Calorimeter (ZDC), the Forward Calorimeter (FCAL), the Multiplicity and Vertex Detector (MVD), the Reaction Plane Detector (RPD), the Resistive Plate

Chambers (RPC), the Silicon Vertex Detector (VTX), and the Forward Silicon Vertex Detector (FVTX). Figure 3.2 depicts the approximate size and position of each of the detectors that are installed in PHENIX as of 2015.

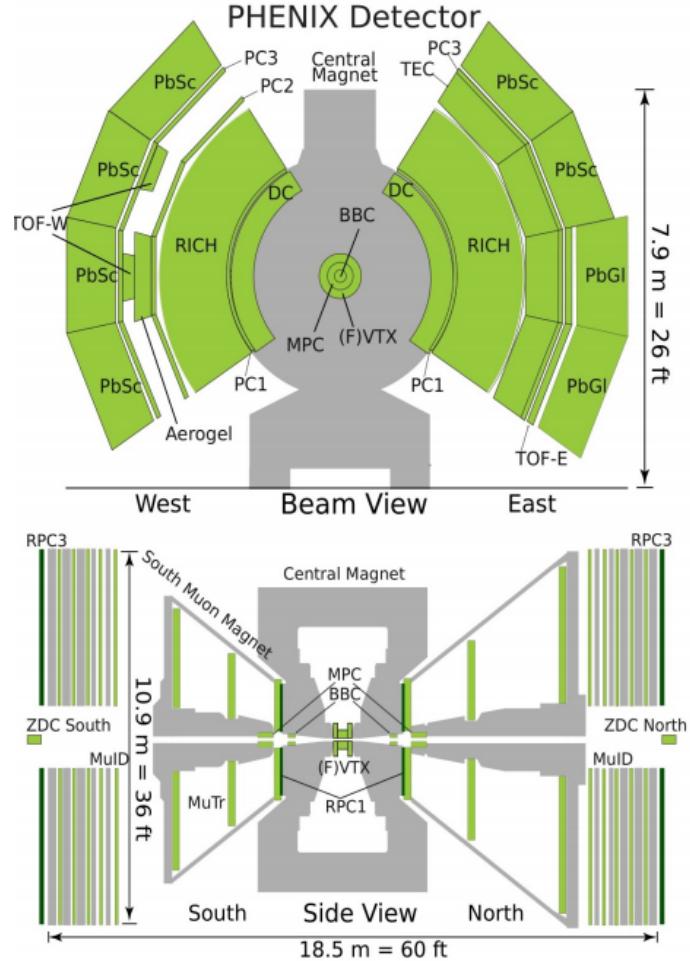

Figure 3.2: A cross section diagram of the PHENIX detector from the incoming beam's perspective (top) and a cross section diagram of the PHENIX detector from the top down (bottom). The central arm detectors are not present in the bottom diagram [21].

For this thesis, the relevant detectors installed in 2015 are the DC, PC, RICH, BBC, and FVTX. The DC, PC, and RICH are located in the mid-rapidity region relative to collisions (Central Arms) and the BBC and FVTX are located in the forward (and backward) rapidity region relative to collisions (Forward Arms) [22].

PHENIX makes use of the three powerful magnets in order to bend charged particles' trajectories: the Central Magnet (CM), the North Muon Magnet (MMN), and the South Muon Magnet (MMS).

PHENIX has a state-of-the art Data Acquisition System (DAQ) which is capable of writing 400 MB/s of information to disk. More details about the PHENIX DAQ are found in section 3.2.8.

For reference, Figure 3.3 depicts the PHENIX coordinate system relative to the RHIC ring. References to the cardinal directions or  $x$ ,  $y$ , or  $z$  are defined in relation to this figure.

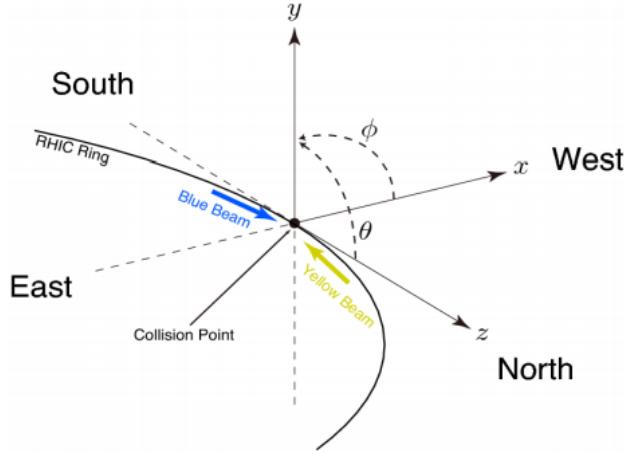

Figure 3.3: The PHENIX coordinate system. The origin is in the middle of the PHENIX detector at the collision point. North and south are parallel to beam axis. East and west are transverse to the beam axis. Central detectors have a west and an east arm on either side of the beam. Forward detectors have a north and a south arm relative to the origin [add ref.](#)

### 3.2.1 PHENIX Magnet System

The CM magnet has two circular coils which can be configured in the same direction (++ or --) or the opposite direction (+-). The +- configuration is used for “zero-field” running which is used for alignment purposes. Figure 3.4 shows the magnetic field lines and strength produced by the PHENIX magnets. The magnetic field lines at mid-rapidity,  $|Z| < 0.3\text{m}$  on the plot, have a peak strength of  $\sim 0.9\text{ T}$  near the beam pipe and are very uniform in direction out to  $\sim R = 2\text{ m}$ . The right panel of 3.4 depicts the magnetic field strength as a function of distance from the center

of PHENIX. For any of the possible CM magnet configurations, the magnetic field strength is very small at 2 m.

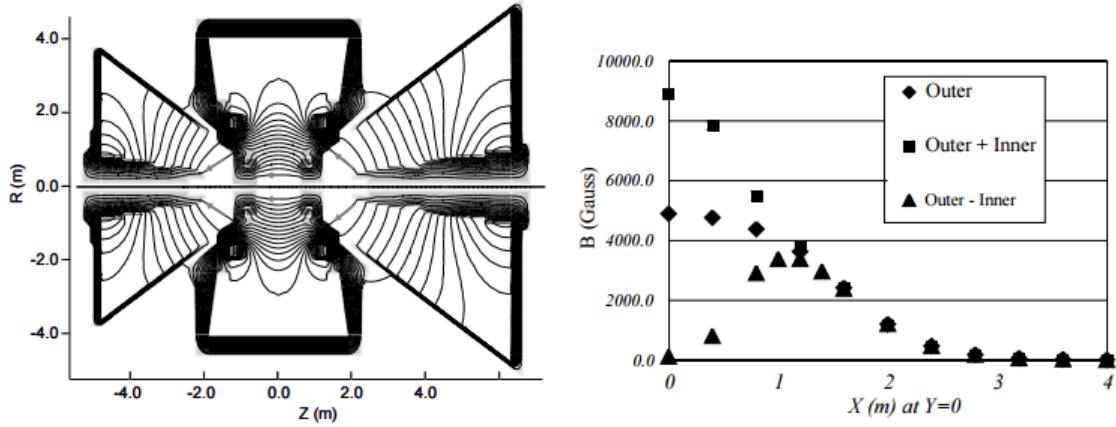

Figure 3.4: PHENIX magnetic field lines from the MMS, CM, and MMN, (left) and the total magnetic field strength from the CM vs the radial distance from the center of PHENIX at  $\phi = 0$   $X$  (right) [12].

### 3.2.2 Beam Beam Counter

The BBC is a forward detector used to determine the event start time, vertex, centrality, and event plane. The BBC is composed of two mirror image arrays, a South and a North Arm, that surround the beam pipe 144 cm on opposite sides of the nominal collision point just behind the Central Magnet, covering  $3.0 < |\eta| < 3.9$  and  $2\pi$  radians in azimuth. Each BBC arm is made of 64 elements each composed of a 3-cm length quartz Cherenkov radiator connected to a 2.5 cm diameter Hamamatsu R6178 mesh dynode PMT (photomultiplier tube), as shown in Figure 3.5. The outer and inner diameters of the BBC are 30 cm and 10 cm, respectively.

The BBC is used to mark the event start time for the entire PHENIX detector by averaging the emitted particles arrival time at each BBC arm. The timing difference between each arm provides an estimate of the collision's z-vertex by

$$z = c \frac{T_S - T_N}{2}, \quad (3.1)$$

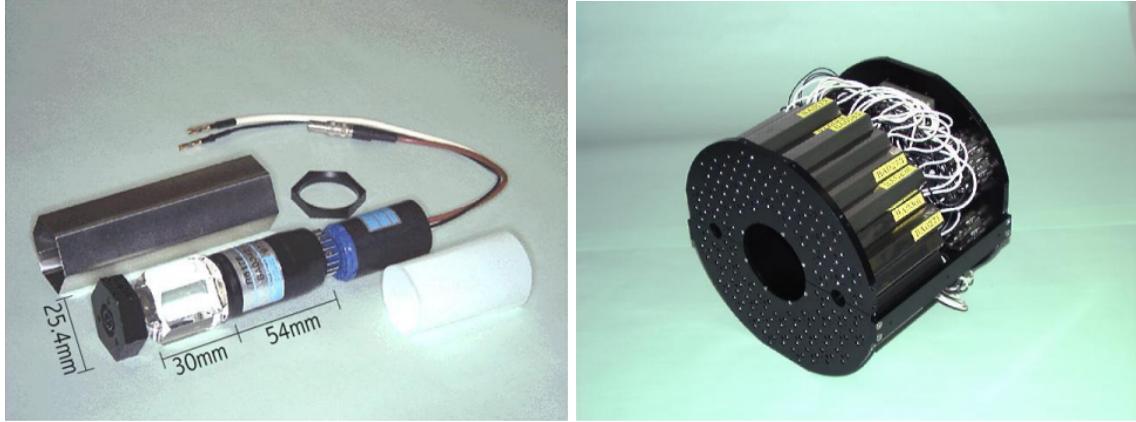

Figure 3.5: Photographs of the BBC detector. The left is of a single detector element consisting of a quartz Cherenkov and a PMT. The right is of one of the BBC arms, consisting of 64 detector elements [22].

where  $T_S, T_N$  are the particle's average arrival times for each arm and  $c$  is the speed of light.

For  $p+\text{Au}$  at  $\sqrt{s_{NN}} = 200$  GeV collisions, the BBC has a timing resolution of  $\text{ps} \sim 40$  ps and a z-vertex resolution of  $\sim 1.0\text{--}2.0$  cm, depending on the event charged particle multiplicity. This rough estimate of the vertex is used during triggering. Specific details about triggers are in section 3.2.8.

The BBC also provides the centrality classification, as described in Chapter 2, Section 2.1.1, of a collision event in PHENIX. Details of how BBC data is used to compute the centrality are given later in this Chapter in section 3.2.10.

### 3.2.3 Forward Vertex Detector

The FVTX is a PHENIX detector upgrade that became operational in 2012 for taking physics data. The FVTX uses charged particle tracking, collision vertex determination, and event plane determination [21]. The FVTX consists of two identical endcaps covering a combined pseudorapidity range of  $1 < |\eta| < 3$  and full azimuth coverage. Each endcap has four stations of silicon mini-strip sensors with a pitch of  $75 \mu\text{m}$  arranged in the radial direction around the beam pipe. The basic unit of construction is a wedge that has a silicon strip sensor and read-out chips. There

are four FVTX layers in each endcap. The inner most layer (on each side) of the FVTX has a smaller radius. Figure 3.6 is a photograph of the FVTX disks and an engineering drawing of the FVTX and support structure. The FVTX is used in this thesis to calculate an event plane.

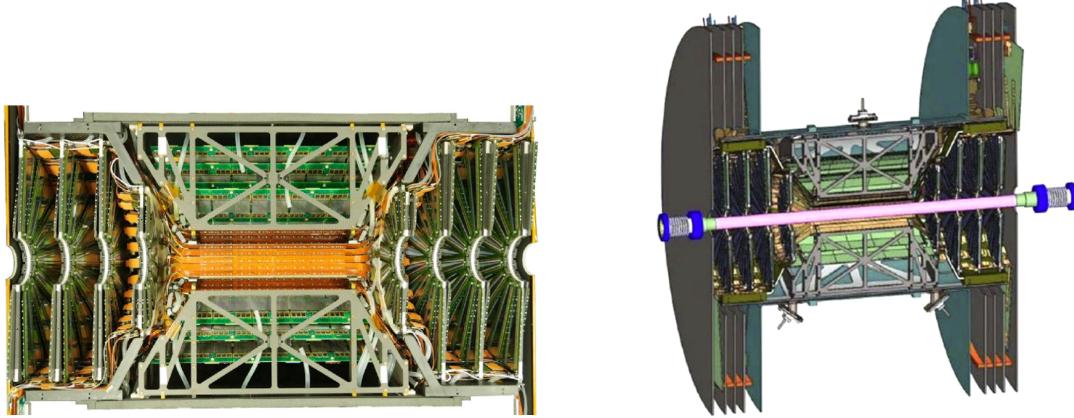

Figure 3.6: A photograph of half of the FVTX. The FVTX are the half disks on either end of the picture (left) and a schematic of the FVTX at a slightly different angle (right). The FVTX is only 20 cm in the  $z$  direction from the PHENIX coordinate system origin (the center of each picture) [21].

### 3.2.4 Drift Chamber

The DC consists of two gas multi-wire chambers, one located in each arm. The DC is used to measure particle trajectories in the  $r\phi$  plane. The DC is located  $\sim 2$  m from the  $z$ -axis, placing it in a very small residual magnetic field from the CM. Apart from the VTX, the DC is the first detector encountered by a particle in mid-rapidity.

As a charged particle passes through the DC volume, the gases are ionized to create free electrons. These electrons cause a chain reaction of ionizations which are measured by an anode wire. The DC is designed in such a way that the drift velocities of the electrons are predictable enough to relate time and position together.

Each identical DC arm is cylindrical in design and covers 2.5 m along the beam direction and is 0.4 m thick as seen on the left in Figure 3.7. A gas mixture of 50% Argon and 50% Ethane

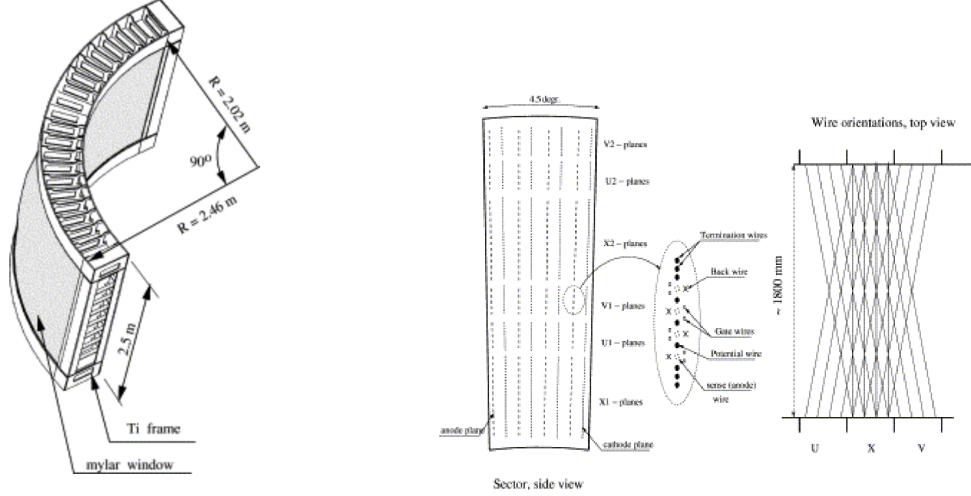

Figure 3.7: A diagram of the DC titanium frame which encloses the detector (left) and a diagram of the X, U, and V wires in the DC (right) [22].

is used in each arm of the DC. Each arm is divided into 20 equal sectors covering 4.5 degrees in  $\phi$ . Each sector contains six types of wire modules stacked radially and labeled X1, U1, V1, X2, U2, V2, respectively, from the inside out. The X wires run parallel to the beam to perform precise  $\phi$  measurements while the U and V wires are set at small angles of about six degrees relative to the X wires to provide information about the z position of the track. A diagram of the wire layout in each sector is shown on the right in Figure 3.7. In total, the DC consists of 6500 anode wires leading to 13,000 readout channels, with a measured single wire resolution of 165 m and a spatial resolution of 2 mm.

### 3.2.5 Pad Chambers

The PCs are multi-wire proportional chambers which consist of three separate layers of detectors measuring precise hit positions in the PHENIX tracking system. The innermost layer, PC1, is located in both the East and West arms immediately outside the DC, providing a measurement of the z position at the back plane of the DC. The second layer, PC2, is located behind the RICH in the West arm only. The outer layer, PC3, is in both arms and provides a second point on the

straight line trajectories of the tracks through the detector, outside of the CM magnetic field as shown in Figure 3.4. PC1 hits are used to reduce the track background.

### 3.2.6 Ring Imaging Cherenkov Detector

The RICH detector is located immediately behind the PC1 and provides the primary electron identification for PHENIX. The RICH consists of two identical detectors in CA. Each detector contains 48 mirror panels which focus Cherenkov light onto PMTs. The RICH is filled with radiator gas, which is CO<sub>2</sub> for the  $p$ +Au running. The RICH provides e/π (electron over pion) discrimination below the π Cherenkov threshold of  $\sim 4$  GeV/c. Figure 3.8 shows the energy over momentum  $E/p$  distribution in Au+Au =  $\sqrt{s_{NN}}$  200 GeV collisions. When RICH hits are required in conjunction with DC tracks, a clear electron signal peak can be seen at  $E/p = 1.0$ .

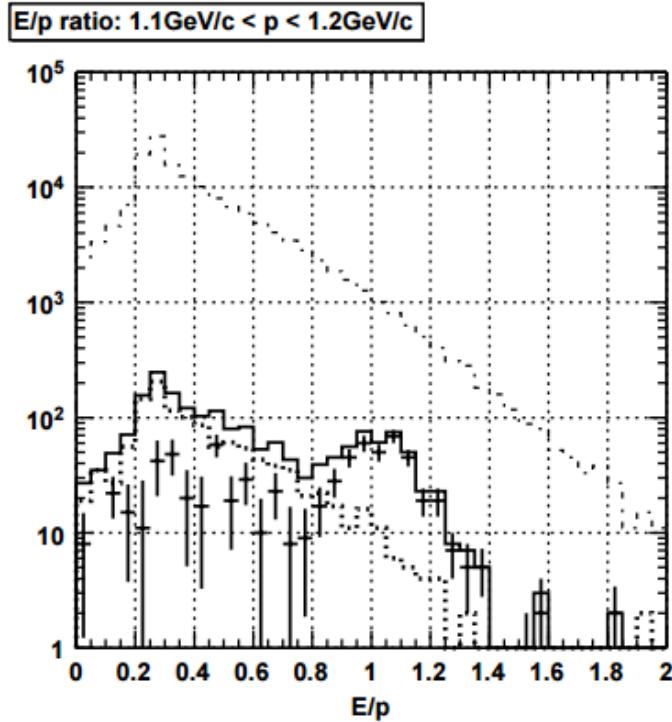

Figure 3.8: Ratio of energy to momentum for all Drift Chamber tracks (dashed-dotted line), and tracks associated with RICH hits (solid line) in Au+Au =  $\sqrt{s_{NN}}$  200 GeV collisions. The  $p_T$  range is given in the title [9].

### **3.2.7 Electromagnetic Calorimeter**

The EMCAL is the outermost subsystem in the central arms and is designed primarily to measure the energies and positions of photons and electrons. It also plays a key role in particle identification, as well as providing triggering because rare events. Two different EMCAL designs were utilized with 6 sectors based on a lead-scintillator design and 2 sectors based on a lead-glass design. The two different designs were chosen deliberately as each provides advantages and disadvantages; for instance the lead glass has a better energy resolution, while the lead scintillator has better linearity and timing.

### **3.2.8 PHENIX Data Acquisition System**

PHENIX makes use of a fast DAQ to manage the transfer and collation of hundreds of kB of event data from over two dozen independent detector subsystems at a rate of over 6 kHz. This amounts to writing to disk hundreds of MB/s, a data writing rate which the PHENIX DAQ consistently achieves for months of constant use.

The collection of a Granule Timing Module (GTM), Front End Modules (FEM), and a Data Collection Modules (DCM) is known as a “granule” and is the minimal combination of DAQ hardware sufficient for data production, as shown in Figure 3.2.8.1. Each detector subsystem’s output data is managed by a granule. Pipelined Field Programmable Gate Arrays (FPGA) with carefully controlled dead time are used to calculate the trigger decisions. The FPGAs are fed information from the experiment. Once the FPGAs compute the trigger decision, the trigger signals are monitored by the GTM. If the trigger decision is positive, the GTMs instruct the FEMs to release their data from their buffers and send them to their granules’ DCM. If the decision is negative, the FEMs are instructed to dump the data. Once the DCM is instructed to send its data downstream, it is sent to the Event Builder (EvB), which will be discussed in an upcoming section.

### 3.2.8.1 Triggering

PHENIX runs 32 distinct trigger simultaneously. Each of the trigger has a scale down number to control the relative bandwidth each trigger receives. To understand the PHENIX triggers, it is useful to learn about the beam clock.

The PHENIX trigger is tied to the clock of the blue beam, one of the two counter circulating rings of which RHIC is comprised. The clock rate is fixed at 9.38 MHz and is tied to the rate at which RHIC overlaps bunches of ions in the interaction regions. Every time a bunch of ions from the blue ring overlap with a bunch of ions from the yellow ring, there is a blue clock trigger. This clock is stable by necessity of the precision required to run a complex accelerator like RHIC. This blue clock trigger is the backbone of PHENIX triggering for there can be no ion collision event if there is no overlap of bunches. Consequently, almost every PHENIX trigger is synchronized with the clock.

The trigger that is usually given the largest bandwidth is the minimum bias (minbias) trigger. As the name suggests, the trigger seeks to mark the detection of an ion collision while reducing to a minimum the bias to the type of the collision . To achieve this, data from the BBC are used. Although what constitutes a minbias observation varies with collision species, the BBC minbias trigger is generally defined as  $>0$  PMTs in each arm above threshold. Not only is this condition a good indication that a ion collision occurred, it is also the minimum information necessary to calculate the collision vertex position using the BBC. The vertex information is important because it is used to select for collisions which occur in the narrow range of acceptance of the current PHENIX detector configuration. This range is  $-10 \text{ cm} < z < 10 \text{ cm}$ . For completeness, PHENIX takes BBC minbias triggers with  $z$  vertex cuts of 30 cm, 10 cm, and with no vertex cut. The collection of all these triggers is what is considered to be the PHENIX minbias trigger.

In Run 15, a high multiplicity trigger was implemented to enhance event statistics for events producing the most amount of particles. This trigger was given a large fraction of the bandwidth and consisted of requiring at least 35 out of 64 PMTs in the south arm of the BBC. More details

about this trigger are located in section 3.2.9.

Table 3.1: An example Run15  $p+Au$  200 GeV relevant trigger configuration and parameters. A trigger's scale down number reduces its rate by  $1/(1+\text{scale down})$ .

<i>Trigger Name</i>	<i>Scale down</i>	<i>Trigger rate</i>	<i>Vertex cut</i>	<i>Part of minbias</i>
<i>Clock</i>	196077	45Hz	N/A	<i>no</i>
<i>BBC(&gt; 0 PMTs) narrowvtx</i>	100	695Hz	10cm	<i>yes</i>
<i>BBC(&gt; 0 PMTs)</i>	2083	88Hz	30cm	<i>yes</i>
<i>BBC(&gt; 0 PMTs) novertex</i>	3959	94Hz	<i>no cut</i>	<i>yes</i>
<i>BBC(&gt; 35 PMTs)</i>	1	1640Hz	10cm	<i>no</i>

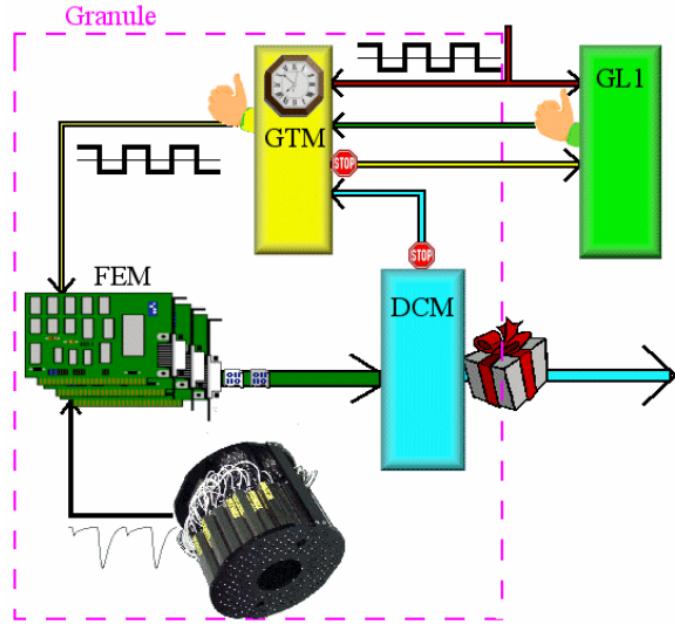

Figure 3.9: Diagram of a granule. Granules are the building blocks of the PHENIX DAQ. Each detector subsystem has at least one granule.

### 3.2.8.2 Event Builder

Following the PHENIX DAQ downstream, after a positive trigger decision has been sent to each of the granules, the granules' data packets are sent from that granule's DCM to the event builder. It is the event builder's job to associate each granule's data packet from the same collision event into one bundle of data known as an event. The event builder consists of Sub Event Buffers

(SEB), Assembly Trigger Processors (ATP), an Event Builder Controller (EBC), and a Gigabit Ethernet Switch as the communication management. The switch transfers the data to long-term storage. Figure 3.10 provides a diagram of how these components are connected.

Granules send the data packets to the specific SEB assigned to that granule. The EBC receives global trigger information and assigns each ATP a specific collision event. The ATP then requests the data from all of the SEBs for the specific event assigned to it by the EBC. Once the ATP is successful, it writes the assembled event to disk and the EBC instructs the SEBs to flush the buffer for that event.

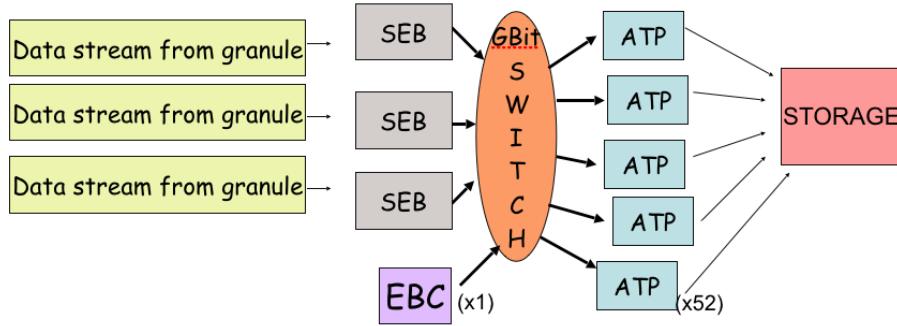

Figure 3.10: Diagram of the event builder.

### 3.2.9 Run 15

Run 15 is the RHIC running period in the year 2015, which marks fifteen consecutive years of RHIC running since the year 2000. Run 15 began in January 2015 and ended in June of 2015. There were approximately eleven weeks of research viable, polarized  $p+p$  collisions at  $\sqrt{s} = 200$  GeV, approximately five weeks of research viable polarized  $p+Au$  collisions at  $\sqrt{s_{NN}} = 200$  GeV, and approximately one week of research viable  $p+Al$  collisions  $\sqrt{s_{NN}} = 200$  GeV. Of interest to this thesis are the  $p+p$  and  $p+Au$  datasets.

In addition to providing the min-bias trigger for Run 15, the BBC was used to implement a high-multiplicity trigger in order to enhance the amount of the top 5% highest multiplicity events. The high-multiplicity trigger requires 35 of the 64 BBC south arm, PMTs to be above threshold in

Table 3.2: Some relevant RHIC parameters from Run 15.

Collision Species	$p+p$	$p+Au$	units
Total Particle Energy	100.2	$103.9 + 100.0$	GeV/nucleon
Ions per Bunch	225	$225 + 1.6$	number $\times 10^9$
Number of Bunches	111	111	number
Luminosity Average Per Fill	$63 \times 10^{30}$	$45 \times 10^{28}$	$cm^{-2}s^{-1}$
Total Delivered Luminosity	382	1.27	$pb^{-1}$
Average Fill Lifetime	8	7	hours

a given event to be satisfied. The relevant BBC arm for  $p+Au$  is the south arm since that is the Au-going direction so the multiplicity is much higher in the south arm. The enhancement can be seen in Figure 3.11.

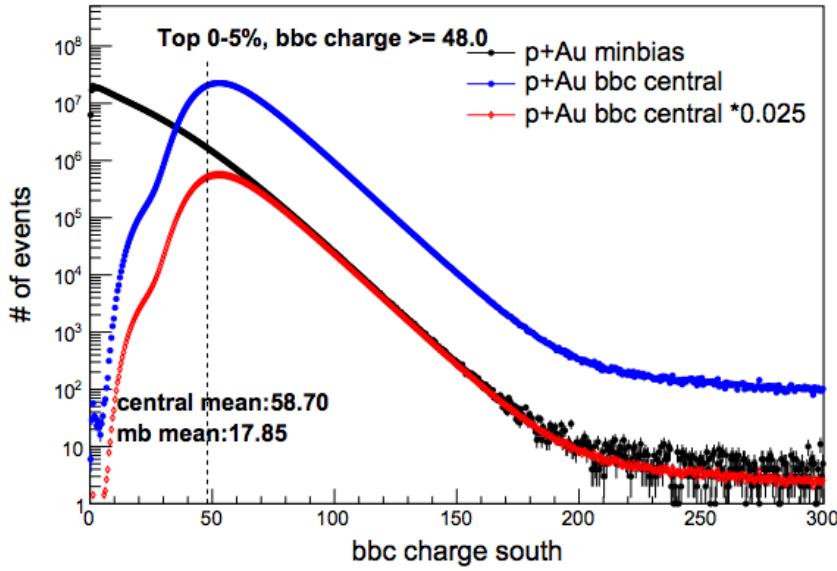

Figure 3.11: The distribution of BBC charges in  $p+Au$  at  $\sqrt{s_{NN}} = 200$  GeV events for different triggers. The black curve is the distribution of charges for the minbias trigger. The blue and red curves are the distributions of charges for the high multiplicity trigger. The red curve being scaled by a factor of 1/40 to show agreement with the black curve. The definition of the top 5% more central events are BBC south charges  $\geq 48.0$ . The plot shows the large enhancement of the number of 0-5% centrality events that are gained using the high multiplicity trigger compared to the number of 0-5% centrality from the minbias trigger alone.

### 3.2.9.1 Beam Collision Geometry

For Run 15  $p+\text{Au}$  200 GeV running, RHIC's blue and yellow beams were not in perfect accordance to the PHENIX coordinate system. This was manifested in two separate ways. First of all, the collision vertex is significantly offset from the z-axis to which all of the PHENIX detectors are aligned. This is a typical situation in PHENIX datasets but it must be addressed. The other effect, and the more significant of the two, comes from the fact that the beams are colliding at an angle of 3.6 milli-radians in the x-z plane, as illustrated in Figure 3.12. This is a result of configuring RHIC magnets for the specific charge to mass ratios of the  $p+\text{Au}$  collision species.

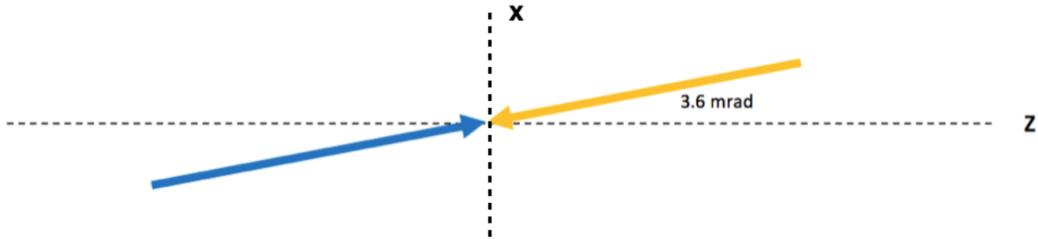

Figure 3.12: A vector diagram illustrating the yellow and blue beam angle confirmation relative to the PHENIX coordinate system.

The collision vertex in x and y is known as the beam center. The beam center varies over the course of data taking but its values on average are  $(x, y) = (0.206, 0.065)(\text{cm})$ . The distribution of z-vertices from collision events can be seen in Figure 3.13. Due to the fact that the beams are colliding at an angle in the x-z plane, the x-component of the beam center will have a z-vertex dependence with a slope of -0.0036 cm of x per 1 cm of z. Apart from how the beam angle effects the beam center values, it also violates the expectation of a uniform  $\phi$  distribution of particles with respect to PHENIX detectors. PHENIX detectors are designed and aligned, with respect to the PHENIX coordinate system, with the expectation of geometric symmetry. A significant beam collision angle with respect to PHENIX detectors would be equivalent to PHENIX detectors being tilted which would violate geometric symmetry. The physics analysis described in this thesis is

sensitive to these beam geometry effects. A discussion on how to account for these effects will be in Chapter 4.

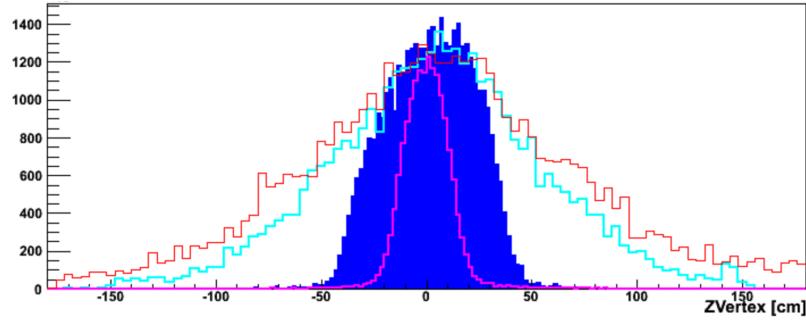

Figure 3.13: The BBC  $z$ -vertex distribution in a typical  $p$ +Au run for different triggers a described in Table 3.1. The teal curve is the BBC(>0 PMTs) novertex trigger, the blue is the BBC(>0 PMTs), and the magenta is the BBC(>0 PMTs) narrowvertex.

### 3.2.10 Centrality Determination

The centrality determination is done by adding up all BBC South (BBCs) (Au-going direction) PMT charges for every event and then splitting up that distribution into equivalent centrality bins. This procedure, which is the same used for  $d$ +Au, is used to associate a centrality bin with number of binary collisions from Monte Carlo Glauber (MC-Glauber), as discussed in Chapter 2 Section 2.3.1.1, + Negative Binomial Distribution (NBD). An example of such MC-Glauber event for d+Au is seen in Figure 3.14.

In this procedure, total BBCs charge assumed to be proportional to the number of binary collisions in a  $p$ +Au collision  $N_{COL}$ , with fluctuations being described probabilistically via the NBD as defined:

$$\text{NBD}(x; \mu, \kappa) = \left(1 + \frac{\mu}{\kappa}\right) \frac{(\kappa + x - 1)!}{x!(\kappa - 1)!} \left(\frac{\mu}{\mu + \kappa}\right)^x \quad (3.2)$$

where  $\mu$  and  $\kappa$  are mean and positive exponent parameters. The NBD was chosen for this situation due to the linear scaling of the NBD parameters, i.e. randomly sampling from  $n\text{NBD}(\mu, \kappa)$  becomes  $\text{NBD}(n\mu, n\kappa)$ . We fold the MC-Glauber with the NBD such that the charge distribution is described

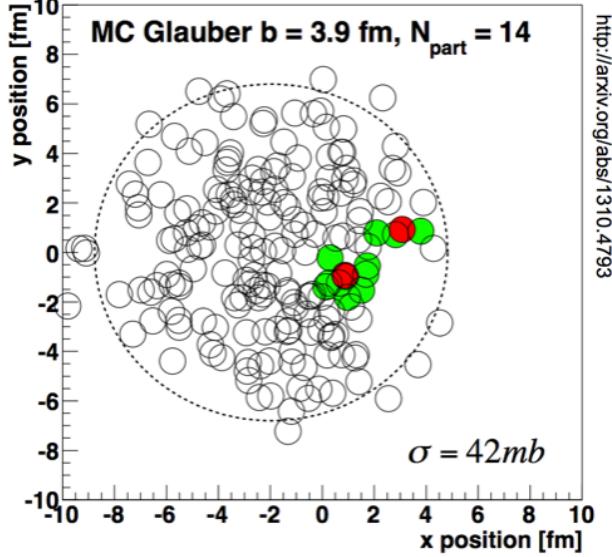

Figure 3.14: A Monte Carlo Glauber d+Au event display. Each circle is a nucleon. The red nucleons are from the projectile (deuteron) and the green nucleons are participants from the target (gold). Glauber counts even a near miss as a full collision [5].

as

$$P(x) = \sum_{n=1}^{N_{COL}^{\max}} \text{Gl}(n) \times \text{NBD}(x; n\mu; n\kappa), \quad (3.3)$$

where  $x$  is the BBCs charge and  $\text{Gl}(n)$  is the event normalized Glauber distribution [5]. The two parameters  $\mu$  and  $\kappa$  are fit to the experimental BBCs charge distribution, as shown in Figure 3.15. This figure shows good agreement between the data and the MC-Glauber + NBD fit. The best fit NBD parameters are  $\mu = 3.14$ ,  $\kappa = 0.47$ .

There is a deviation at small BBCs charge because the minbias trigger is inefficient due to the fact that a PMT must be hit in both the BBC South and North. The bottom panel of Figure 3.15 is the ratio of the data to the theory curve shows that the agreement is good at a charge of 10 and greater. This ratio is fit to determine the minbias trigger efficiency as it “turns on.” This fit has good agreement with the turn-on curve which can be integrated to determine that the minbias trigger is 84% efficient. By combining the theoretically determined  $p$ +Au cross section with the 84% trigger efficiency, we determine the total inelastic  $p$ +Au cross section  $\sigma = 1.76$  barnes.

Thus, centrality is defined as a percentage of the total inelastic cross section.

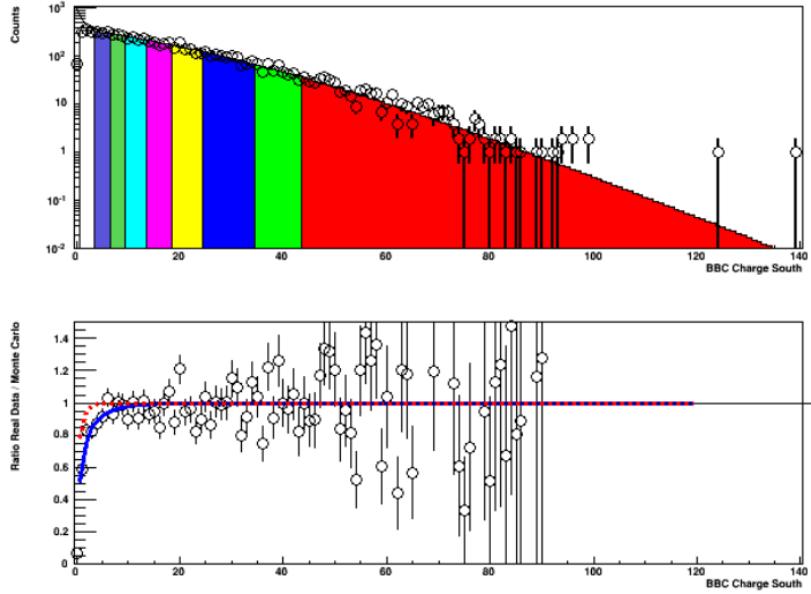

Figure 3.15: Real data for BBCs charge shown as open circles and MC-Glauber + NBD (top). The colors correspond to the various percentiles relative to the total inelastic  $p+\text{Au}$  cross section, from right to left: 0–5%, 5–10%, 10–20%, 20–30%, 30–40%, 40–50%, 50–60%, 60–70%, and 70–84%. The blue and red curves correspond to the minbias trigger efficiency in all inelastic collisions and inelastic collisions producing a particle at mid-rapidity, respectively (bottom).

## Chapter 4

### Analysis

This chapter is an extensive discussion of the information and data analysis techniques used to extract the measurement. First we will describe about the building blocks of the  $v_2$  measurement, then we will examine the event plane analysis techniques, and the systematic errors.

#### 4.1 The Building Blocks of the Measurement

Prior to any analysis, the raw data collected by various PHENIX subsystems must be reconstructed into well-defined software objects encapsulating the physical properties of the particles that traversed the detector. Although we have already discussed the subsystems used in this analysis in Chapter 3, this section provides in-depth information on central arm tracks, FVTX clusters, and BBC photomultiplier tubes (PMTs), and the physics variables they contain. Figure 4.1 displays the coordinate system for PHENIX and the particle parameters that are in relation to it.

##### 4.1.1 Central Arm Tracks

Central arm (CA) tracks are the representation of charged particles emitted from the heavy ion collision, which are detected by detectors in the PHENIX central arms. There are two central arms, each one covering an acceptance of  $\eta < |0.35|$  and  $\frac{\pi}{2}$  in pseudorapidity and azimuth, respectively. The relevant detectors for this analysis include the Drift Chamber (DC), the Pad Chambers (PC) and the Ring Imaging Cerenkov (RICH) detector. As previously discussed, the drift chamber provides momentum information; the pad chambers provide track quality metrics; and the RICH

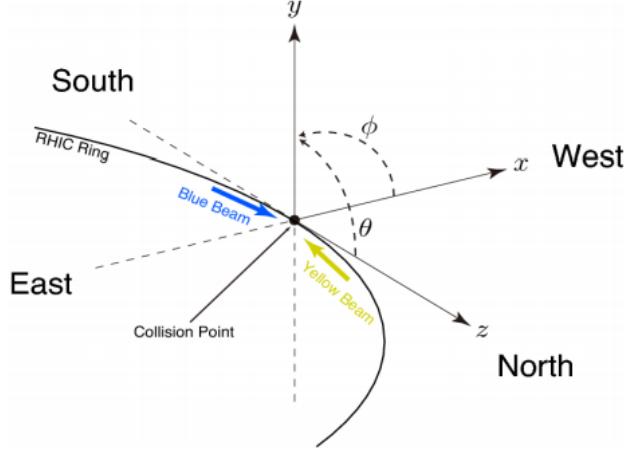

Figure 4.1: Reference coordinate system for the PHENIX detector. The origin is set at the collision point, around which the detector is centered. The beam runs parallel to the (longitudinal)  $z$ -axis, where the direction of positive  $z$  is defined as **north**. The **east** and **west** directions are defined as perpendicular to the longitudinal direction, where the direction of positive  $x$  is defined as west.

provides electron identification.

The main physical parameter of CA tracks is the momentum vector  $\vec{p} = (p_x, p_y, p_z)$  of the particles, defined at the collision vertex. This analysis uses tracks with momentum  $0.02 < |p_T| < 3.5$  GeV/ $c$ , where the momentum resolution is good, as shown in Fig. 4.6. The azimuthal angle and pseudorapidity of the track are calculated from the components of its momentum vector, as follows:

$$\phi = \arctan\left(\frac{p_y}{p_x}\right), \quad (4.1)$$

$$\eta = \text{ArcSinH}\left(\frac{p_z}{p_T}\right). \quad (4.2)$$

Table 4.1: Quality categorization of CA tracks, as a function of PC1 and DC wire hits. The quality parameters used in this analysis are 31 and 63.

Quality	PC1 found	PC1 unique	UV found	UV unique
17,18,19	1	0	0	0
21,22,23	1	0	1	0
29,30,31	1	0	1	1
49,50,51	1	1	1	0
61,62,63	1	1	1	1

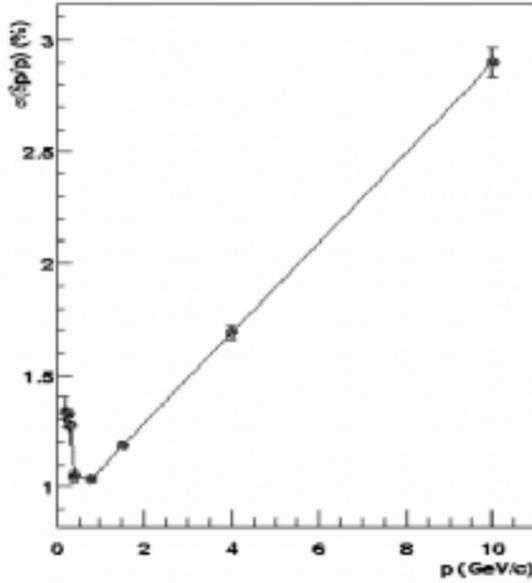

Figure 4.2: Momentum resolution  $\sigma_p/p$  as a function of the reconstructed track momentum,  $p$  for simulated single-particle events[1].

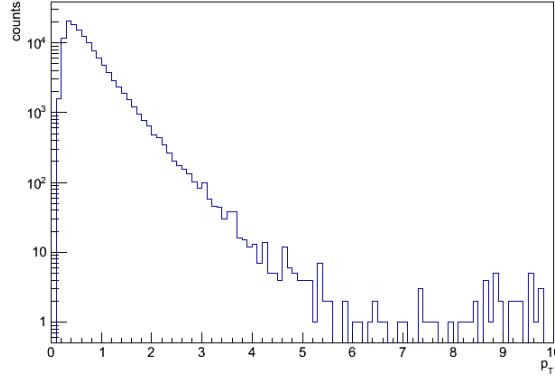

Figure 4.3: Transverse momentum  $p_T$  distribution of CA tracks in  $p+Au$  events at  $\sqrt{s_{NN}} = 200$  GeV. High  $p_T$  tracks observed correspond to unsubtracted background.

Table 4.2: Quality categorization of CA tracks, as a function of DC wire momentum information. The quality parameters used in this analysis are 31 and 63.

Quality	X1 used	X2 used
17,21,29,49,61	1	0
18,22,30,50,62	0	1
19,23,31,51,63	1	1

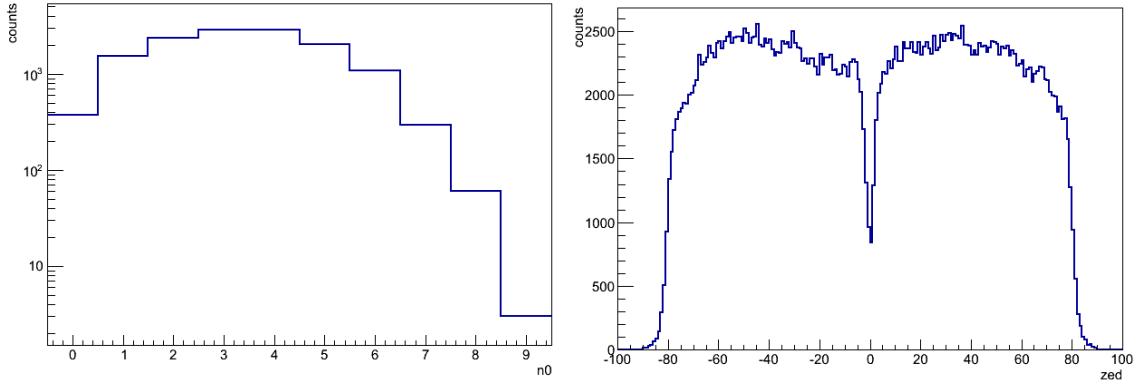

Figure 4.4: The distribution of (left)  $n0$ , i.e., the number of PMTs fired in the RICH, and (right)  $zed$ , i.e., the longitudinal position of tracks in the DC, for CA tracks in 0-5% central  $p$ +Au events at  $\sqrt{s_{NN}} = 200$  GeV. The structure observed in the  $zed$  distribution corresponds to a gap in the detector acceptance.

In addition to momentum, CA tracks provide a number of other parameters that can be used to ensure the quality of tracks and isolate a sample corresponding to charged hadrons. These include  $zed$  in the DC,  $d\phi$  and  $dz$  in the PC,  $n0$  in the RICH, and the general track quality calculated from DC and PC information. These variables are defined as follows:

- The  $zed$  variable corresponds to the longitudinal position of the track in the DC, as shown in Fig. 4.4
- The  $dphi$  and  $dz$  variables quantify the distance between a track projection and its associated hits in the PC. In order to make standard cuts on these variables, their distribution must be calibrated to a standard Gaussian in a procedure known as signalization, described in subsection 4.1.1.1
- The  $n0$  variable, used for electron identification, corresponds to the the number of PMTs fired in the RICH that match the DC track projection, as shown in Fig. 4.4

Table 4.3: Central Arm Track Cuts.

<i>variable</i>	cuts	units
<i>p</i>	$0.02 < p < 10.0$	GeV/c
zed	$ zed  < 75$	cm
PC3 d $\phi$	$ d\phi  < 2.0$	radians $\times 10^9$
PC3 dz	$ dz  < 2.0$	cm
n0	$n0 \leq 0$	count
quality	63 or 31	N/A

#### 4.1.1.1 Sigmalization of PC Variables

The goal of PC variables  $dz$  and  $d\phi$  is to provide criteria to determine if the  $\phi$  orientation and  $z$ -direction of the track match between the third layer of the PC and the DC. The sigmalization is done in the minimum bias sample and is valid for all other centrality selections. We did the sigmalization procedure for tracks in different transverse momentum bins, separately in the east and west arms, and for positive and negative particles. The  $d\phi$  and  $dz$  distributions were fitted with a double-Gaussian function and then the parameters were smoothed as a function of  $p_T$ . Fig. 4.1.1.1 a) shows a fit to the sigmalized  $d\phi$  distribution, and Fig. 4.1.1.1 b) shows a fit to the sigmalized  $dz$  distribution for tracks with  $1.0 < p_T < 1.1$  (GeV/c) in both the west and east arms as well as both positively and negatively charged particles. Then we fit the signal Gaussian mean and sigma by some polynomial functions. Once these variables had been sigmalized, we selected only the tracks within a  $2\sigma$  cut.

#### 4.1.2 FVTX Clusters

The FVTX consists of four silicon layers in the north and south directions, covering an acceptance of  $1 < |\eta| < 3$  and spanning the full azimuth. FVTX clusters correspond to the spatial location where charged particles hit one of the silicon layers. Each cluster is expected to correspond to a single charged particle in the case of  $p$ +Au collisions, because of the low multiplicity relative to Au+Au collisions. These clusters have a spatial resolution in  $x$  and  $y$  of 50  $\mu\text{m}$ , and have an RMS along the  $z$ -direction that corresponds to the width of an FVTX layer, of  $\frac{200}{\sqrt{12}} \mu\text{m}$  [21]. Due to the

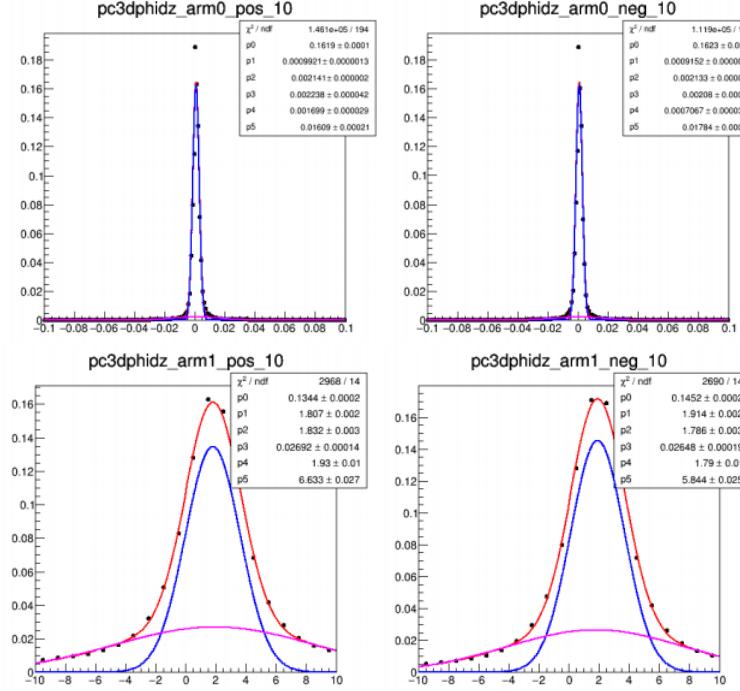

Figure 4.5: The top plots show the PC3 matching  $d\phi$  fit in range  $1.0 < pT < 1.1$  (GeV/c). The blue and pink lines are single Gaussian fits to the signal and background, respectively, which are combined in the red line. The bottom plots show the result of the  $dz$  sigmalization, done in the same way as for  $d\phi$ .

$p$ +Au collision system's inherent asymmetry, the majority of particles are produced in Au-going (i.e., south) direction. Taking into account this asymmetry, only the clusters from the south arm are used for calculations in this analysis. In a typical 0-5% centrality event, there are on average 1500 FVTX clusters in the south arm alone.

#### 4.1.3 BBC PMTs

The BBC provides information on the position, time of arrival, and number of charged particles that hit the BBC's quartz radiator material. The BBC acceptance is  $3.1 < |\eta| < 3.9$  and spans the full azimuth. The resolution of the detector in  $x$  and  $y$  is 5 cm, corresponding to the diameter of a BBC PMT. As with the FVTX, the  $z$  resolution is simply the width of the active area of the BBC divided by  $\sqrt{12}$ . In addition to spatial information, the BBC provides charge

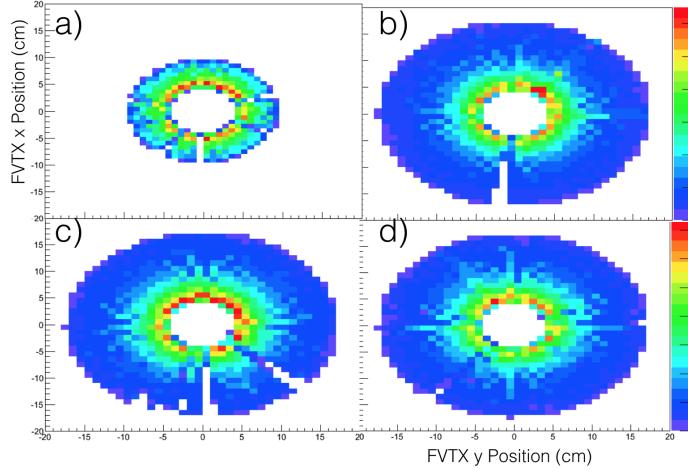

Figure 4.6: Distribution of FVTX clusters in  $x$  and  $y$  for layers 1, 2, 3, and 4 for panels a), b), c), and d), respectively. The color scale corresponds to the number of counts.

information, calibrated so that a value of 1.0 corresponds to a single charged particle hitting the detector. Fig 4.7 shows the layout of the PMTs for the BBC. As discussed in section ??, the information regarding arrival time and particle charge can be used to calculate the  $z$ -vertex of the collision.

## 4.2 The Event Plane Method

Some details of the event plane were given in Chapter 2 Section 2.2.4. The goal of this thesis is to measure  $v_2$ , which is related to collective behavior as evidenced by correlations among particles. These correlations exist relative to the orientation of the collision. The event plane method measures the azimuthal anisotropy in final state particles. The event plane method uses final state particles to calculate the event plane angle from the data. A different set of final state particles are used to define the event plane and measure the  $v_2$ .

An event plane angle is defined for each harmonic, and is denoted as  $\Psi_n$  where  $n$  is the harmonic number. The definition for  $\Psi_n$  is related to the calculation of the Q-vector. For an event with  $N$  particles, define the flow vector  $\vec{Q}$  as follows:

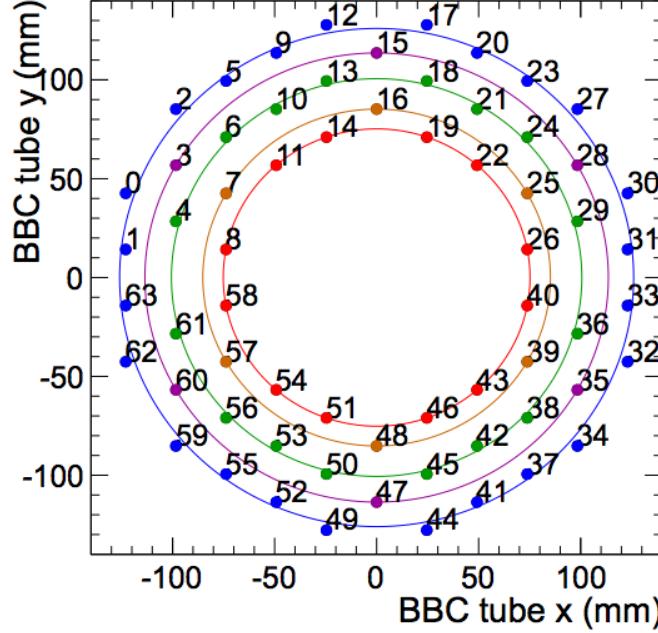

Figure 4.7: Diagram showing the positions of the PMTs for the BBC-south detector. Rings shown with the same color indicate PMTs at an approximate common radius.

$$Q_x = \sum_i^N (w_i * \cos(n * \phi_i)) \quad (4.3)$$

$$Q_y = \sum_i^N (w_i * \sin(n * \phi_i)) \quad (4.4)$$

$$Q_w = \sum_i^N (w_i) \quad (4.5)$$

where  $i$  is the  $i$ th particle in the event,  $\phi_i$  is the azimuthal angle of the particle,  $w_i$  is the weight factor, and  $n$  is the harmonic number. We define the  $n$ th order event plane as  $\Psi_n = \arctan\left(\frac{Q_y}{Q_x}\right)$ .

Once the event plane has been calculated, the flow harmonics ( $v_n$ ) are defined as

$$v_n = \frac{\langle\langle \cos(n(\phi - \Psi_n)) \rangle\rangle}{\text{Resolution}(\Psi_n)}, \quad (4.6)$$

where  $\langle\langle \rangle\rangle$  indicates that  $\cos(2\phi - \psi)$  is averaged over all particles in the same event, and the resulting  $v_2$  must be averaged over many events [44]. Note, the event plane angle and the q-vector are defined at the event level,  $v_2$ .

As discussed in Chapter 2, Section 2.2.4, the event plane angle is a measurement which attempts to correspond to the physical reaction plane angle. Thus, the event plane is an imperfect representation of the reaction plane which needs to be corrected. This correction is known as the event plane resolution  $Res(\Psi_n)$ , and is calculated using the 3-subevent method. It is important to note the the set of particles used to calculate  $\Psi_n$  and  $\phi$  must be different in order to avoid autocorrelations. This is usually done by imposing a large  $\eta$  gap (usually at least a half of a unit of pseudorapidity) between the two particle sets.

For this analysis, the event plane is calculated separately for each of the forward detectors mentioned above, i.e., the BBC and the FVTX. For the FVTX, the Q-vector is calculated in each event as

$$Q_x = \sum_i^{N_{Clus}} (\cos(n * \phi_i)) \quad (4.7)$$

$$Q_y = \sum_i^{N_{Clus}} (\sin(n * \phi_i)) \quad (4.8)$$

$$\phi_i = \arctan\left(\frac{Clus_y^i}{Clus_x^i}\right) \quad (4.9)$$

where  $N_{Clus}$  is the number FVTX clusters in that event and  $Clus_{y,x}^i$  are the  $x$  and  $y$  components of the  $i$ th FVTX Cluster in that event. At this point, this Q-vector is calculated with no cluster dependent weight factor because each cluster is taken to be equal weight.

For the BBC, the Q-vector is calculated in each event as

$$Q_x = \sum_i^{N_{PMT}} (w_i \cos(n * \phi_i)) \quad (4.10)$$

$$Q_y = \sum_i^{N_{PMT}} (w_i \sin(n * \phi_i)) \quad (4.11)$$

$$Q_w = \sum_i^{N_{PMT}} (w_i) \quad (4.12)$$

$$\phi_i = \arctan\left(\frac{PMT_y^i}{PMT_x^i}\right) \quad (4.13)$$

where  $w_i$  is the charge collected on the PMT and  $N_{PMT}$  is the number of PMTs that fired (above threshold) in each event.

Finally, the  $v_n$  are calculated using a combination of the BBC or FVTX Q-vectors and the CA tracks as

$$v_n = \frac{\langle\langle \cos(n(\phi^{CA} - \Psi_n^{BBC,FVTX})) \rangle\rangle}{Resolution(\Psi_n^{BBC,FVTX})}. \quad (4.14)$$

In this analysis, we are concerned only with measuring the second-order harmonic  $v_2$ .

#### 4.2.1 Event Plane Resolution Calculation

As mentioned above, the event plane resolution is calculated using the standard 3-subevent method[44]. The strategy of this method is to measure  $\Psi_2$  with three different detectors in the same event, in order to better constrain the overall measurement of  $\Psi_2$ . The event plane resolution is defined as

$$Res(\Psi_2^A) = \sqrt{\frac{\langle\langle \cos(2(\Psi_2^A - \Psi_2^B)) \rangle\rangle \langle\langle \cos(2(\Psi_2^A - \Psi_2^C)) \rangle\rangle}{\langle\langle \cos(2(\Psi_2^B - \Psi_2^C)) \rangle\rangle}}, \quad (4.15)$$

where A,B, and C are three detectors measuring the same event. Here, the term “subevent” refers to the specific subset of particles measured by a given detector, assuming no decorrelation [44].

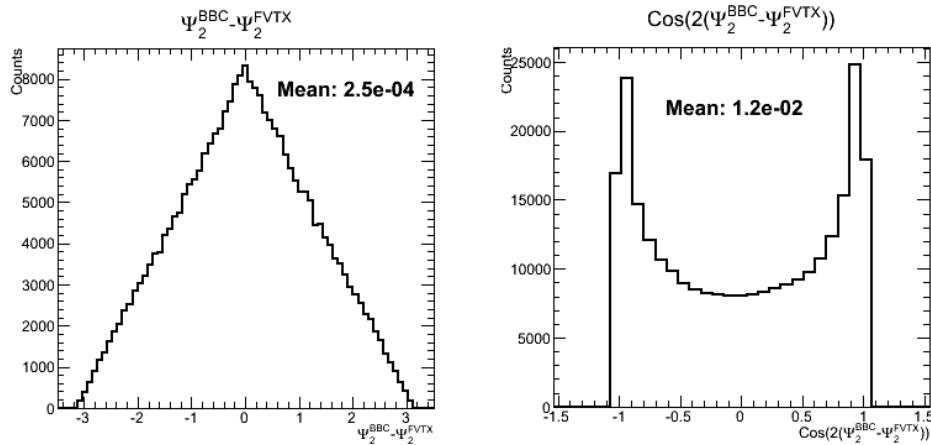

Figure 4.8: Intermediate steps involved in calculating the event resolution. (left) Raw difference between the event plane angles for two different detectors. This distribution is triangular because it is the result the cross-correlation of two uniform distributions,  $\Psi_2^{FVTX}$  and  $\Psi_2^{BBC}$ . (right) The cosine of two times the difference between the two event plane angles. The average of this distribution is used in equation 4.15.

In this analysis, the three detectors used to provide the required three subevents are the

FVTX-south, the BBC-south, and the CA, which span pseudorapidity acceptances of  $-3 < \eta < -1$ ,  $-3.9 < \eta < 3.1$ , and  $|\eta| < 0.35$ , respectively. Unlike the BPCS and the FVTXS, the CNT detector does not have full azimuthal acceptance coverage. Therefore, the event plane angle cannot be reliably calculated with this detector for events whose event plane points outside of the acceptance. In order to solve this problem, we calculate the event plane resolution using a different, yet mathematically equivalent formulation that does not make use of  $\psi_{CNT}$ , as given below:

$$Res(\Psi_n^A) = \sqrt{\frac{\langle\langle \cos(n(\Psi_n^A - \phi^{CNT})) \rangle\rangle \langle\langle \cos(n(\Psi_n^A - \Psi_n^C)) \rangle\rangle}{\langle\langle \cos(n(\phi^{CNT} - \Psi_n^C)) \rangle\rangle}}, \quad (4.16)$$

where there is a double average over each CNT track and each event.

Table 4.4:

Detector	$n = 2$	$n = 3$
FVTXs	0.216	0.010
BBCs	0.052	0.010

#### 4.2.2 Event Plane Flattening Calibration

In order for the event plane to be useful in making a  $v_n$  measurement, the event plane angle must be calibrated such that its distribution is uniform. For the event plane method, a physical assumption is made that the true distribution of  $\Psi_n$  angles will be uniform. In other words, there is no preferred event plane angle in heavy ion collision. If the measured  $\Psi_n$  distribution is not flat, we attribute that behavior to variations in the efficiency of detecting charged particles as a function of  $\phi$ . Thus, the event plane calibration procedure seeks to correct for these non-uniformities in acceptance, and restore the  $\Psi_n$  distribution to the physical expectation of uniformity. We employ a procedure to re-center and flatten the measured non-uniform  $\Psi_n$  distribution, such as the one shown in Figure 4.2.2.

The red curve in Fig. 4.2.2 depicts a significant deviation from uniformity in the  $\Psi_2$  distribution. The flattening calibration attempts to correct for this lack of uniformity by shifting

the  $\Psi_2$  value of each individual event by an amount corresponding to the deviation of the overall distribution for all events. Although this procedure results in a uniform  $\Psi_2$  distribution, applying too large of a correction arising from an exceedingly distorted initial distribution can lead to systematic effects on the  $v_2$  measurement, which will be discussed in the next section. Therefore, it is important to address any systematic effects that would affect the uniformity of the  $\Psi_2$  distribution.

The flattening calibration requires two steps to completely flatten the  $\Psi_n$  distribution. The first step of the calibration is to re-center the mean of the raw  $\Psi_n$  distribution to be at 0.0 radians and to resize the RMS. The second step is to Fourier transform the re-centered distribution and use the transformation to shift the  $\Psi_n$  values to a uniform distribution. With flattening, each  $\Psi_n$  is transformed to  $\Psi_n + \Delta\Psi_n$ .  $\Delta\Psi_n$  is defined as

$$\Delta\Psi_n = \sum_{i=1}^N \left( \frac{2}{i} (\sin(i\Psi) F_i^{\cos}(f(\Psi_n)) - \cos(i\Psi) F_i^{\sin}(f(\Psi_n))) \right), \quad (4.17)$$

where  $N$  is the number of components,  $F_i^{\cos}(f(x))$  is the  $i$ th component of the cosine Fourier transform of  $f(x)$ , and  $f(\Psi_n)$  is the  $\Psi_n$  distribution. For this analysis,  $N = 12$  is a sufficient number of components to flatten the  $\Psi_n$  distribution. The re-centering and flattening calibration is done in separate 30 z-vertex bins.

### 4.3 East West $v_2$ Discrepancy

As discussed in the previous section, distortions in the raw  $\Psi_2$  distribution can cause distortions in the measurement of  $v_2$ . In this section, we discuss how the beam alignment effects the raw  $\Psi_2$  distribution and how it can be corrected for.

As shown in Fig 4.10,  $v_2$  is different when measured using tracks in the west ( $-1 < \phi < 1$ ) and east arm ( $2 < \phi < 4$ ) of the CA. This is a systematic effect explained by the colliding beams not being parallel to the longitudinal axis of PHENIX. When examining beam alignment effects on the  $v_2$  measurement, we can quantify the east west  $v_2$  asymmetry by calculating  $R_{v_2}$  which is

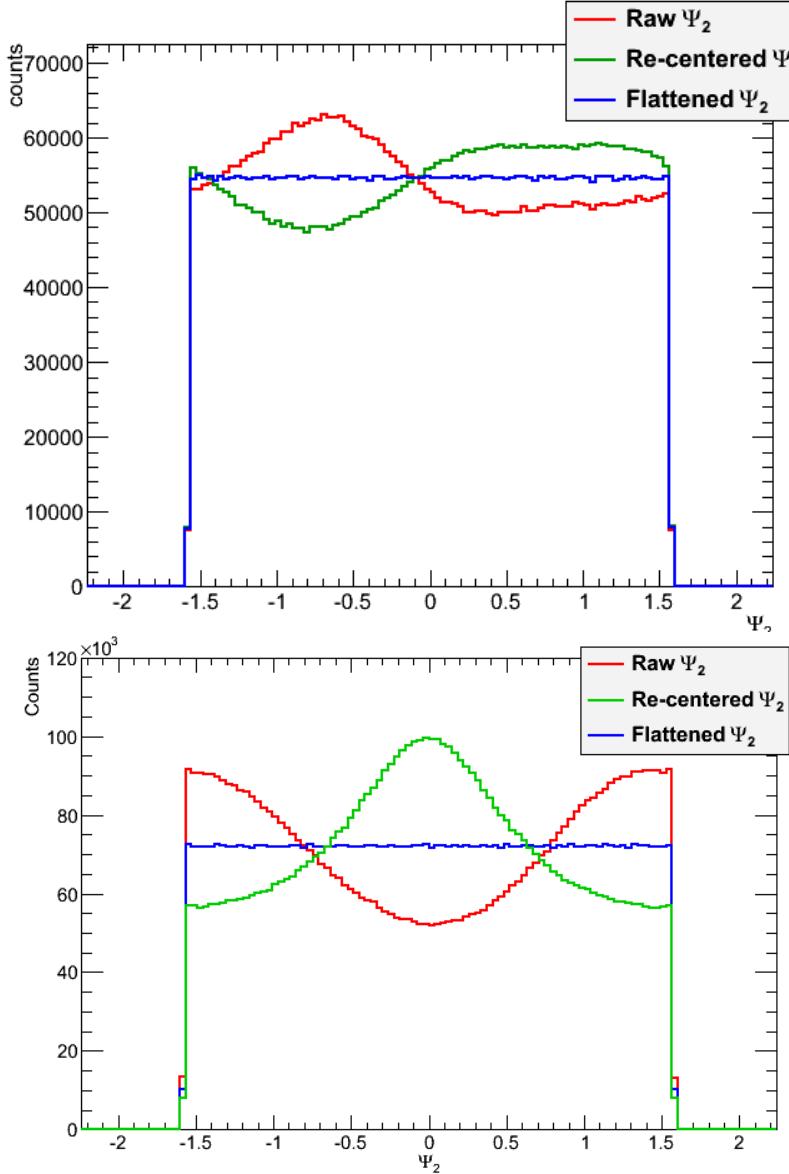

Figure 4.9: This is the  $\Psi_2$  distribution projected over all z-vertex bins at different steps during the calibration. The top is from the FVTX south and the bottom is from the BBC south. The range of the  $\Psi_2$  resolution is from  $-\frac{\pi}{2}$  to  $\frac{\pi}{2}$  because of the periodicity. The raw (in red)  $\Psi_2$  distribution has a sinusoidal shape. The re-centered (in green)  $\Psi_2$  distribution moves the mean. The flattened (in blue)  $\Psi_2$  distribution spreads out the counts so that there is uniformity. Each calibration step preserves the integral.

calculated by:

$$R_{v_2} = \frac{\sum_{p_T} v_2^{east}(p_T)}{\sum_{p_T} v_2^{west}(p_T)}. \quad (4.18)$$

In Figure 4.12,  $R_{v_2^{FVTX_s}}$  can be extracted by taking the ratio of the numbers in the legend of the

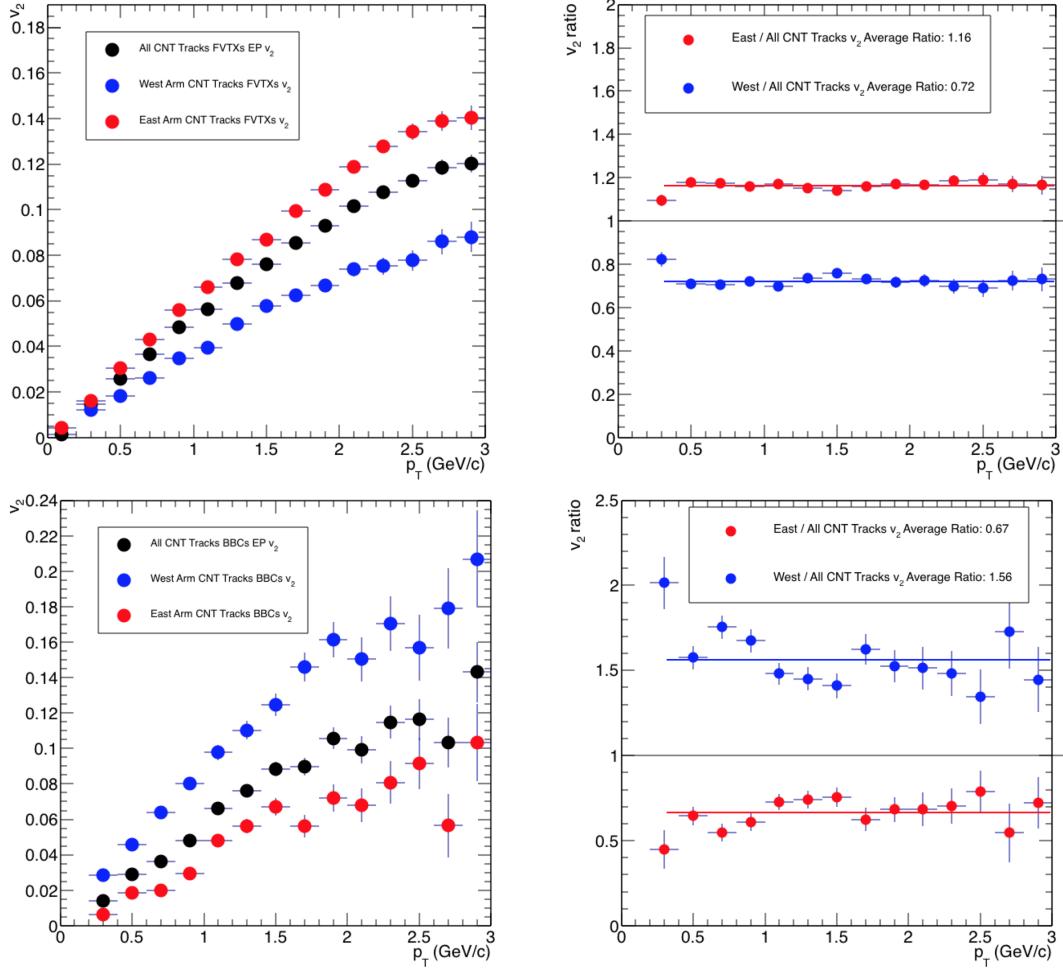

Figure 4.10: First attempt at measuring  $v_2(p_T)$  with the event plane as calculated with the FVTXs (top left) and the BBCs (bottom left) in the  $p+\text{Au}$  at  $\sqrt{s_{NN}} = 200$  GeV dataset, using the default resolution as shown in Table 4.4. The black points show  $v_2$  measured using all CNT tracks. The blue and red points show  $v_2$  measured using only tracks in the west and east arms, respectively. The ratios are fit with a constant, whose value is shown in the legend.

upper right plot and  $R_{v_2^{BBCs}}$  can be extracted the same way for the numbers in the bottom left plot's legend. The  $R_{v_2^{FVTXs}} = 1.61$  while the  $R_{v_2^{BBCs}} = 0.43$ , indicating large east west asymmetry in both measurements, although the  $R_{v_2^{BBCs}}$  is bigger. It is interesting to note that the splitting of the east and west  $v_2$  measurements goes in opposite directions for the BBCs as opposed to the FVTXs. To understand where the discrepancy in these  $v_2$  measurements comes from, we examine the effects of the beam alignment on the  $v_2$  measurement.

#### 4.4 Correcting for the Effects of Beam Alignment

First of all, the collision vertex is significantly offset from the  $z$ -axis to which all of the PHENIX detectors are aligned. The other beam geometry effect, and the more significant of the two effects, comes from the fact that the beams are colliding at an angle of 3.6 milli-Radians in the  $x$ - $z$  plane as shown in Fig. 4.11 [2]. The reason a non-ideal beam geometry creates an east west  $v_2$  measurement difference is because of the assumption that the ideal event plane angle is azimuthally isotropic during the event plane flattening calibration. In the translated and rotated frame where the beams are aligned with the  $z$ -axis the event plane distribution would be uniform, but in the lab frame the event plane distribution in  $\phi$  would have regions of enhancement and reduction. The event plane flattening calibration algorithm restores a non-uniform distribution to a uniform one; however, if the true event plane distribution is non-uniform then forcing the measured distribution to be uniform would produce systematic errors.

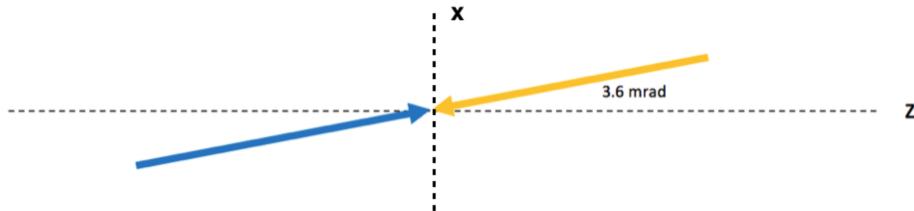

Figure 4.11: Diagram illustrating the angle at which the yellow and blue beams collide relative to the longitudinal  $z$ -axis of the detector. The yellow beam corresponds to the Au (south-going) beam, and blue corresponds to the proton (north-going) beam. Due to a necessity of running  $p$ +Au collisions at  $\sqrt{s_{NN}} = 200$  GeV at RHIC, the beams collide at an angle of 3.6 mrad.

We correct for the offset of the collision vertex by shifting the origin of the PHENIX global coordinate system to the true collision vertex. To correct for the effect of the beam angle, we apply a global rotation of the PHENIX coordinate to align its longitudinal axis with that of the beams. In practice, these transformations are accomplished by individually applying a global rotation and translation to every CA track, FVTX cluster, and BBCs PMT.

As shown in Fig 4.12, applying these corrections prior to calculating  $v_2$  reduces the magnitude of the east-west discrepancy. The new  $R_{v_2^{FVTXs}} = 1.43$ , while the  $R_{v_2^{BBCs}} = 0.66$ , which is a reduction from east-west difference measured without any corrections. However, even after rotating the PHENIX global coordinate system to be in alignment with the beam axis, due to the fact  $\Psi_2$  is a derived quantity, there is a residual effect from the beam rotation which still effects the  $v_2$  measurement.

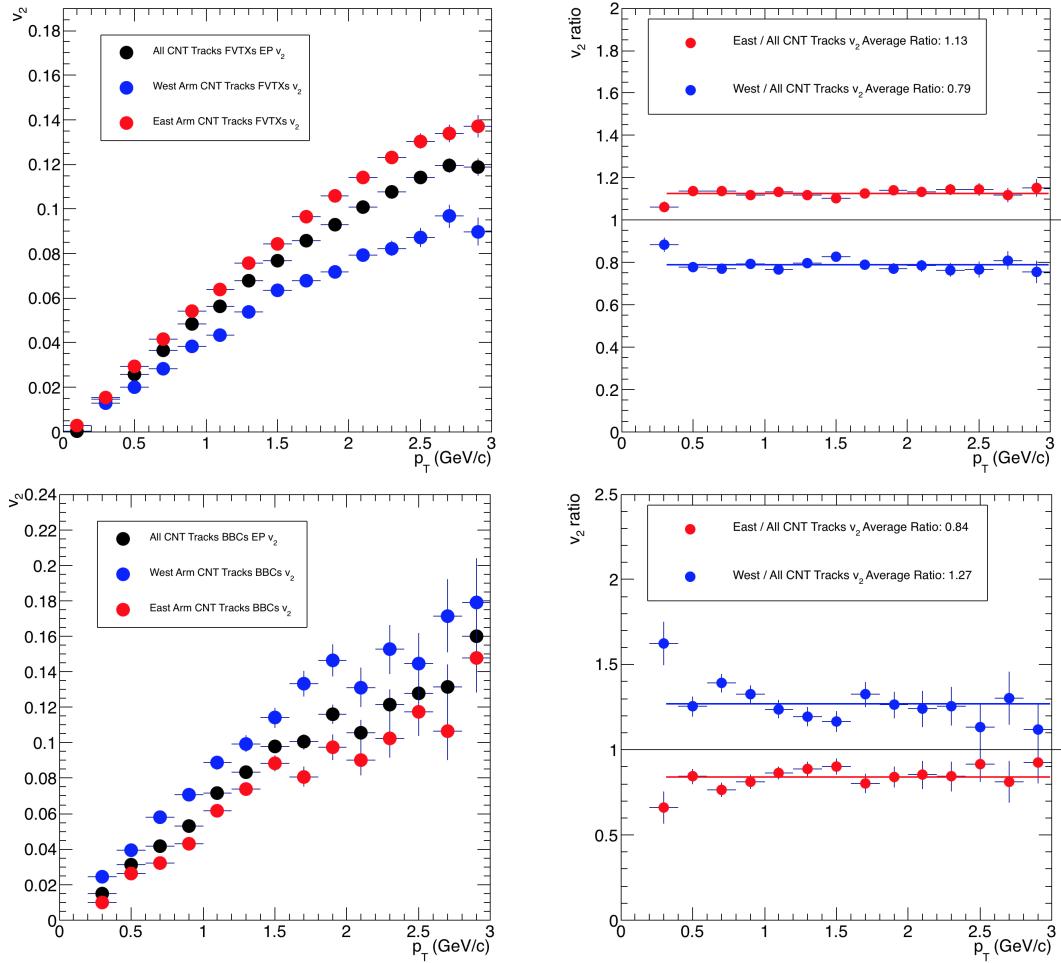

Figure 4.12: A corrected measurement of  $v_2$  as a function of  $p_T$  with the FVTXs (top two panels) and the BBCs (bottom two panels) event plane for the  $p+\text{Au}$   $\sqrt{s_{NN}} = 200$  GeV dataset. The default resolution as shown in table 4.4 is used. The plotting conventions are the same as described in the caption of Fig 4.10.

To explain this effect, consider a cylindrical disk with a hole in the middle, centered about

the z-axis (in analogy to the shape of the FVTX and the BBC), as shown in the left plot of Fig 4.13. In this geometry, all points along a ring of constant radius are at the same pseudorapidity. However, if one were to tilt that disk, the pseudorapidity of points along that ring would be  $\phi$  dependent. The tilt of the disk changes its pseudorapidity acceptance and its extent. Now consider that it is not the disk that is tilted but rather the beam orientation that is tilted. The previous statements about the effect on the  $\eta$  range being  $\phi$  dependent still apply.

The combination of the  $\eta$  acceptance changing, and the  $\eta$  distribution of charged particles not being flat means that the average amount of charged particles going through the disk would be systematically  $\phi$  dependent, as illustrated in Fig 4.13. If the average charged particle distribution is not uniform in  $\phi$ , the event plane distribution will not be either. This results in the flattening procedure creating systematic effects such as the east-west  $v_2$  asymmetry.

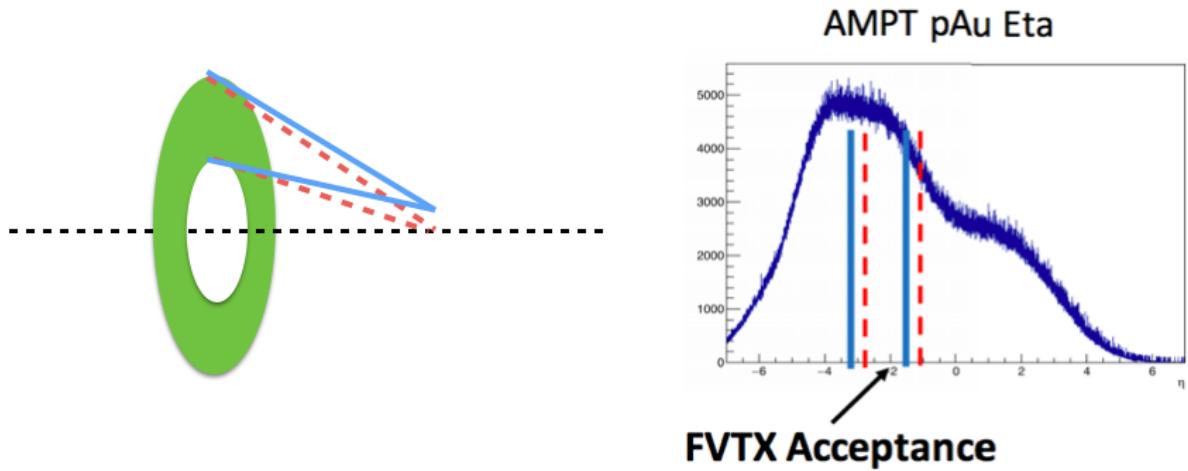

Figure 4.13: (left) Cartoon diagram illustrating  $\eta$  acceptance shift due to a beam offset in one of the FVTXs layers. (right) Pseudorapidity distribution of charged particles from the AMPT Monte Carlo generator for  $p+\text{Au}$   $\sqrt{s_{NN}} = 200$  GeV, showing the shift in  $\eta$  acceptance.

In order to correct for this effect, an additional weight factor is introduced for FVTX clusters and BBC PMTs during the event plane calculation. This factor is such that hits in  $\phi$  regions with systematically less particles are given a larger weight, and correspondingly, hits in  $\phi$  regions with systematically more particles are weighted less. The introduction of this weighting as defined below

does not formally change the event plane calculation, as a weight factor is already implemented in its construction. The modified weight factor is:

$$w_i = w_i^D * F(\phi, \text{Vertex}_Z) \quad (4.19)$$

where  $w_i^D$  is the default weighting associated with the detector element, and  $F(\phi, \text{Vertex}_Z)$  is the multiplicative weighting to correct for the beam geometry.  $F(\phi, \text{Vertex}_Z)$  is dependent on  $\text{Vertex}_Z$ , in addition to  $\phi$ , because  $\eta$  is dependent on the collision vertex. One can analytically calculate this  $\phi$  dependent weight factor using the geometry of the FVTXs and BBCs as well as using the  $\eta$  distribution of charged particles. Unfortunately, the  $\eta$  distribution of charged particles in  $p+\text{Au}$   $\sqrt{s_{NN}} = 200$  GeV has not been measured by an experiment, so we must rely on models that may be inaccurate.

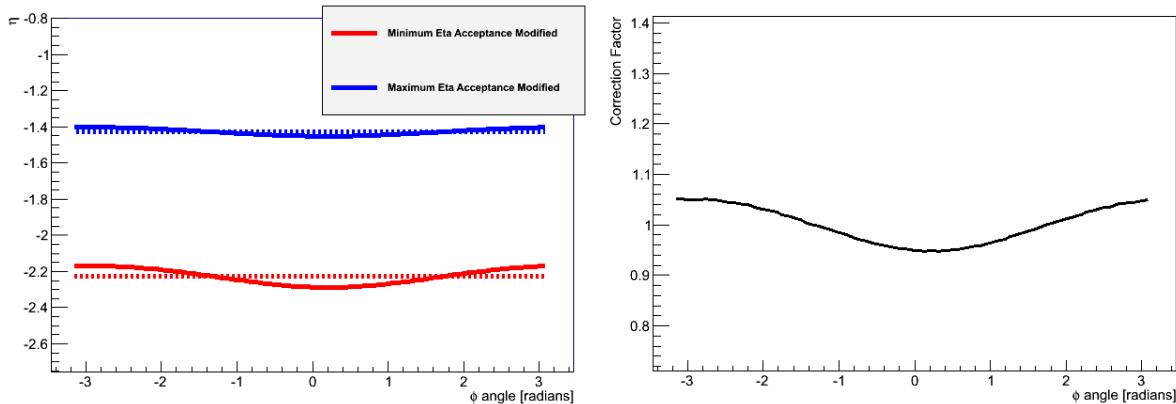

Figure 4.14: The left is the modification of the  $\eta$  acceptance as a function of  $\phi$  for the FVTX first layer. The right is the calculated correction factor from this modification.

Another way to determine the weight factor is to use a data driven method of measuring to what extent each  $\phi$  region in a detector has systematically more or less particles. Then an inverse weighting based on this measurement is applied to the  $\phi$  regions to correct the detector's  $\phi$  distribution to uniformity. The precise implementation of measuring and applying the uniformity of the  $\phi$  regions in a detector will be examined further in the following sections.

#### 4.4.1 FVTX Inverse Phi Weighting

For this method, the weight factor is determined by plotting all hits in a cylindrical disk detector vs  $\phi$ , normalizing this distribution to one, and then inverting it. Applying this weight factor to the data will produce uniform hit distributions in  $\phi$  in the detectors in which it is applied. This will, in turn, make the event plane distribution more uniform when measured in those detectors, thus correcting for the effect. The added benefit of using this method is also correcting for hot and cold  $\phi$  regions in the detector. In order to get rid of significant hot or cold  $\phi$  regions,  $\phi$  regions with weight factors greater than 1.5 or less than 0.5 are set to 0.0. This correction is done for each FVTX layer, in z-vertex bins, and per run. The multiplicative weight function  $F(\phi, \text{Vertex}_Z)$  for the FVTX disks is defined as

$$F(\phi, \text{Vertex}_Z, \text{layer}) = \frac{\langle N_{\text{CLUS}}(\text{Vertex}_Z, \text{layer}) \rangle}{N_{\text{CLUS}}(\phi, \text{Vertex}_Z, \text{layer})}, \quad (4.20)$$

where  $N_{\text{CLUS}}(\phi, \text{Vertex}_Z, \text{layer})$  is the number of FVTX clusters as a function of  $\phi$ ,  $\text{Vertex}_Z$ , and FVTX layer and  $\langle N_{\text{CLUS}}(\text{Vertex}_Z, \text{layer}) \rangle$  is the  $\phi$  average of the number of clusters. The weighting can be seen in Fig 4.15. A comparison between the FVTX weighting and the analytic correction is shown. The good agreement indicates the validity of the weighting.

#### 4.4.2 BBC Charge Weighting

For the BBC, we used another data driven method to correct for the non-uniform particle distribution. Using the distribution of particles in the BBC from the 2015 p+p  $\sqrt{s} = 200$  dataset as a baseline, we applied an inverse weighting much like the method described in the previous paragraph. In the p+p dataset, there was no issue with beam colliding at an angle and the average charge across all 64 PMTs in the BBCs is uniform. In this method, the multiplicative weight function  $F(PMT, \text{Vertex}_Z)$  for the BBCs is defined as:

$$F(PMT, \text{Vertex}_Z) = \frac{\langle N_{\text{Charge}}^{p+p}(\text{Vertex}_Z) \rangle}{\langle N_{\text{Charge}}^{p+\text{Au}}(PMT, \text{Vertex}_Z) \rangle}, \quad (4.21)$$

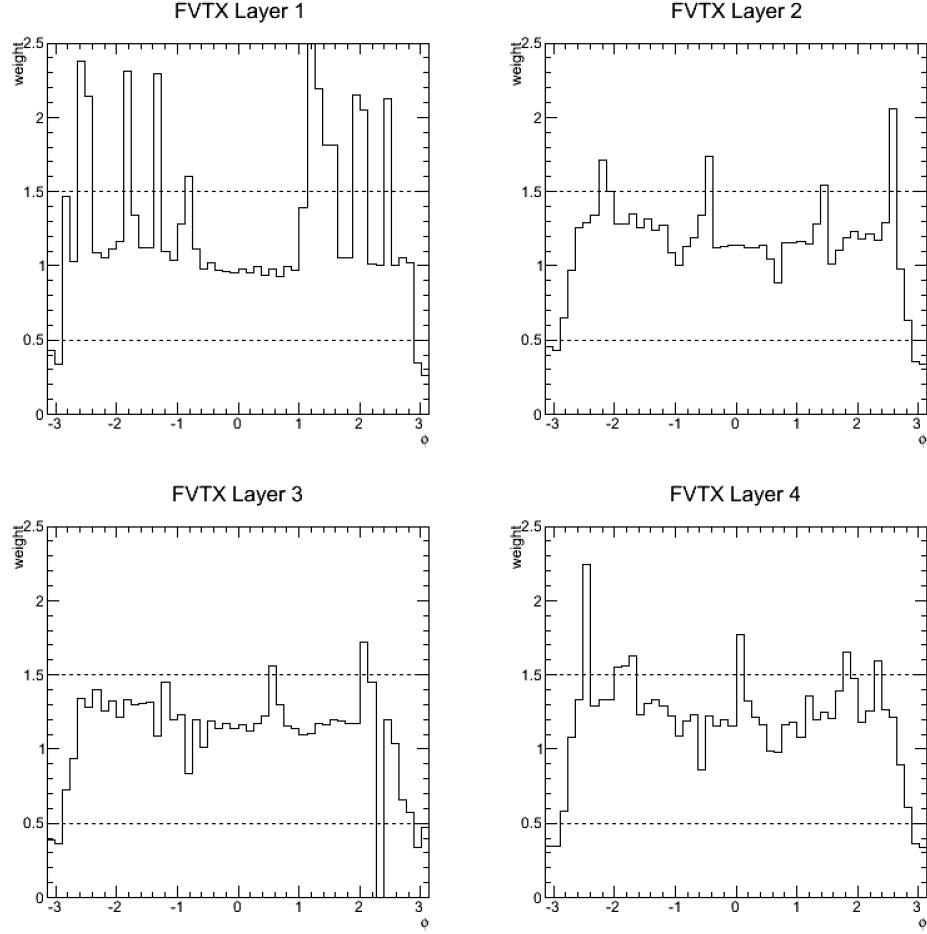

Figure 4.15: These four panels show the FVTX  $\phi$  dependent cluster weighting when calculating the FVTX event plane for each layer separately for events with a collision vertex in  $z$  is around 0. There are some  $\phi$  regions where weight factor is outside of the dotted line bounds. This indicates that either there was a severe deficit or excess of clusters measured in the region. Later, we will examine the effect of keeping these regions or cutting them out on the  $v_2$  measurement.

where  $\langle N_{Charge}^{p+p, p+Au}(PMT, Vertex_z) \rangle$  is the event averaged charge as a function of PMT and  $Vertex_z$  for the p+p and p+Au datasets respectively. This weight function is shown in Fig 4.17 and is applied directly to the event plane calculation using Eqns 4.19 and 4.13. Although the weight function could be defined as a function of  $\phi$  like in the FVTX case, the positions of the PMTs in the BBC are fixed and it is more direct to take the ratio between PMTs.

One effect of using this weighting method is that it will make the distribution of particles in the BBC in  $\phi$  and  $\eta$  uniform. This can be illustrated by looking at Fig 4.18. It is apparent that the

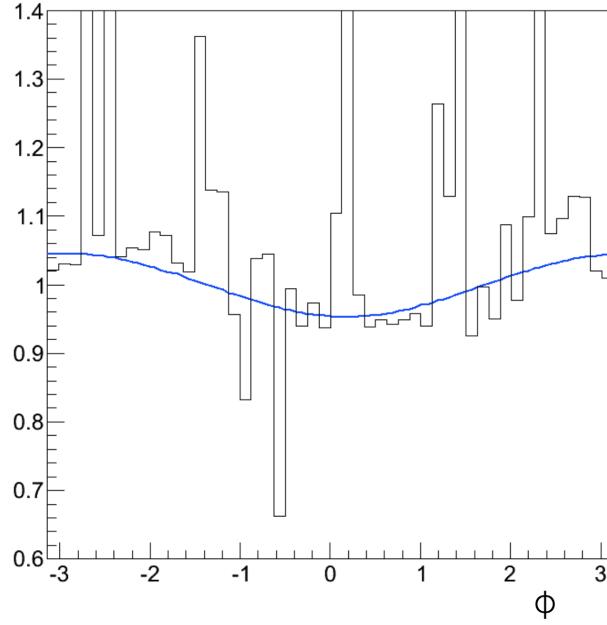

Figure 4.16: The black is the FVTX weighting and the blue is the analytic weighting. They have good agreement.

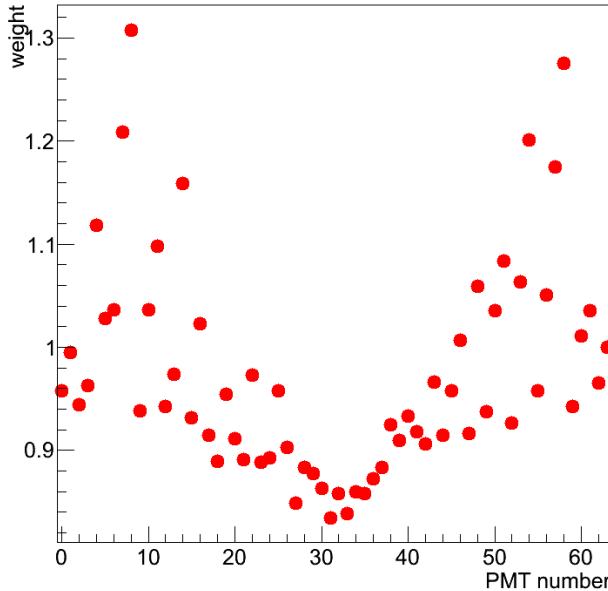

Figure 4.17: Shown here is BBC the multiplicative weight factor  $F$  used when calculating the modified event plane for events where the collision vertex in  $z$  is around 0. The y-axis is the weight factor and the x-axis is the PMT number for the BBCs (there are 64 total in the BBCs).

$p+p$  average charge is much more uniform than the  $p+Au$  average charge as a function of  $\phi$  and

ring. After applying the  $p+p/p+Au$  ratio weighting, which is essentially dividing the left plot by the right plot in Fig 4.18, the PMT charges in ring 1 for the  $p+Au$  dataset will be deweighted so that their corrected average charge will be uniform in  $\phi$ , and in agreement with the average charge for the other rings. If all the BBC rings have the same average charge, this means that the average charge as a function of  $\eta$  for the BBC will be approximately uniform. This is one reason why this method ( $p+p/p+Au$  ratio weighting) is preferred for the BBC, because the variations in the average charge between the rings are normalized. One could apply the FVTX method of inverse  $\phi$  weighting by inverting the right plot of Fig 4.18 to find the weight function. However, although using only the  $p+Au$  dataset would normalize the average charge as a function of  $\phi$ , it would not normalize the charge as a function of  $\eta$ . Both methods applied to the data are shown in the next section but the  $p+p/p+Au$  ratio method does better.

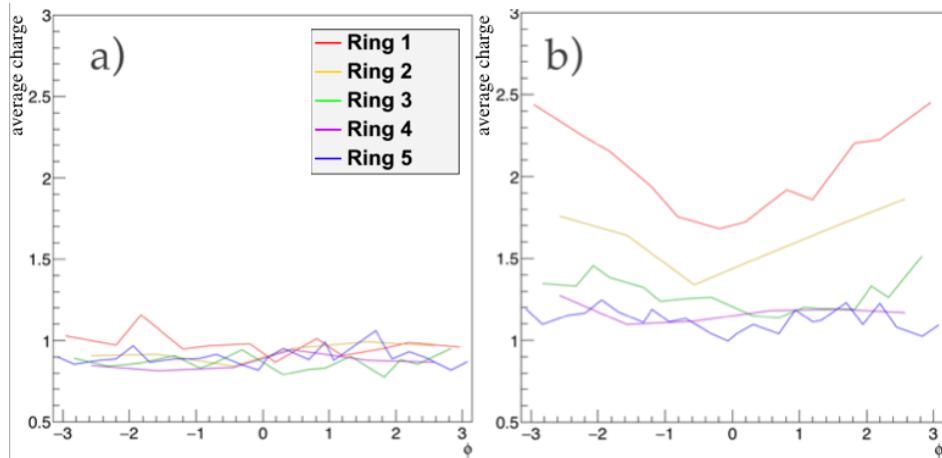

Figure 4.18: These plots depict the average PMT charge per event versus  $\phi$  in the a) the  $p+p \sqrt{s} = 200$  GeV and b)  $p+Au \sqrt{s_{NN}} = 200$  GeV. The PMTs are separated by color, which corresponds to the rings of approximate common radius as shown in Fig 4.7. The left plot shows near uniformity as a function of  $\phi$  and ring. However, the right plot shows a significant deviation from uniformity especially for the innermost rings (rings 1 and 2). In addition to the  $\phi$  variation for the right plot, the innermost rings have the largest average charge when compared to the other rings. This is in part due to the fact the innermost rings cover the a slightly larger  $\eta$  range. However, the innermost rings in the left plot also cover the largest  $\eta$  range and do not exhibit this separation in rings.

#### 4.4.3 Applying Weighting to $v_2$

The previously discussed corrections are applied when calculating the raw  $\Psi_2^{FVTXs}$  used in the  $v_2$  measurement. Shown in Figure 4.19 is the correction summary for the FVTXs  $v_2$  measurement where  $R_{v_2^{FVTXs}}$  is the y-axis. The first column, which corresponds to  $R_{v_2^{FVTXs}}$  calculated using FVTXs layers 1, 2, and 4, with layer 3 being excluded, is explained shortly. The black, red, blue, and green points correspond to no weighting, analytic weighting, inverse  $\phi$  weighting, and inverse  $\phi$  weighting with cuts, respectively. Compared to the  $R_{v_2^{FVTXs}}$  calculated with no weighting,  $R_{v_2^{FVTXs}}$  calculated with each of the corrections brings the ratio quantity much closer to 1.0, indicating the weighting techniques are working. In order to better understand the effect of the corrections,  $R_{v_2^{FVTXs}}$  is measured separately with each FVTXs layer. The rationale for this exclusion is due to FVTXs layer 3's unusual behavior in relation to the other FVTXs layers. As we go from layer 1 to layer 4, the  $R_{v_2^{FVTXs}}$  generally is trending downward except for layer 3. Although the reason for this was never definitively determined, it is likely there is something wrong with the layer data due to electronic or detector problems. Thus, the measurement of  $v_2^{FVTXs}$  is calculated without any clusters in the third layer.

Similarly, Figure 4.20 is the correction summary for the BBCs  $v_2$  measurement where  $R_{v_2^{BBCs}}$  is the y-axis. The first column corresponds to  $R_{v_2^{BBCs}}$  calculated using all five BBCs rings. Compared to the  $R_{v_2^{BBCs}}$  when calculated with no weighting,  $R_{v_2^{BBCs}}$  when calculated with the data driven and p+p/p+Au ratio weighting is modestly closer to 1.0. By looking at  $R_{v_2^{BBCs}}$  calculated with PMTs in individual BBCs rings for the weighted points,  $R_{v_2^{BBCs}}$  is generally trending downward as a function of ring number. Applying the weighting corrections to  $R_{v_2^{BBCs}}$  calculated by ring 1, the innermost ring, over-corrects  $R_{v_2^{BBCs}}$ . This may be explained by the fact that ring 1 covers the largest  $\eta$  acceptance range, causing the correction to be inconsistent. The reason why ring 1 is not excluded from the inclusive  $v_2$  calculation, like FVTXs layer 3 excluded, is because there is no reasonable justification to exclude it other than its over-corrected  $R_{v_2^{BBCs}}$  values. While FVTXs layer 3 breaks the trend of  $R_{v_2^{FVTXs}}$  decreasing, BBCs ring 1 follows the  $R_{v_2^{BBCs}}$  ring trend.

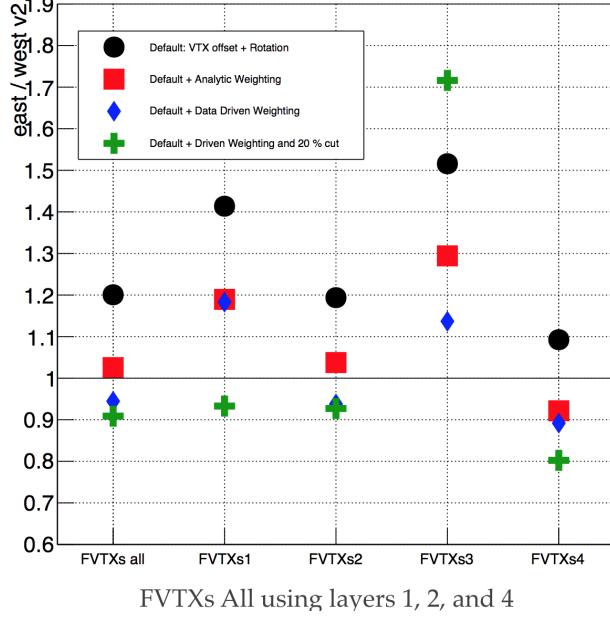

Figure 4.19: Plotted is the FVTXs correction summary where the y-axis is the east/west  $v_2$  ratio and the x-axis is the different subset of clusters used to calculate the  $v_2$ . The black markers correspond to the default corrections. The red boxes correspond to the corrections with the analytic weighting shown in Fig 4.14. The blue diamonds are the FVTX inverse  $\phi$  weighting as shown in section 4.4.1. Finally, the green crosses correspond to the same as the blue diamonds except an additional hot-cold filter of 20% was applied. The first column is using all the FVTXs layers except for the 3rd layer (explained in the text). So the first columns should be approximately the average of columns 2, 3, and 5. Columns 2 through 5 show the ratio calculated from clusters only in that layer.

Fig 4.21 shows the  $v_2(p_T)$  with the inverse  $\phi$  weighting and 20 % cut from Figure 4.19. This figure also shows  $v_2(p_T)$  with the pp/pAu ratio weighting from Fig 4.20. Although the east and west  $v_2^{BBCs}$  measurements do not collapse together like the east and west  $v_2^{FVTXs}$  measurements, the result is good enough to reduce our systematics uncertainty. Due to the fact that  $R_{v_2^{FVTXs}}$  is corrected to within  $\pm 10\%$  and the fact that  $v_2^{FVTXs}(p_T)$  has smaller a statistical uncertainty, the primary  $v_2(p_T)$  measurement is done using the FVTXs.

## 4.5 Systematic Uncertainties

The dominant systematic uncertainties associated with the  $v_2(p_T)$  measurement are as follows: (1) track background from photonic conversions and weak decays, which we estimate at 2%

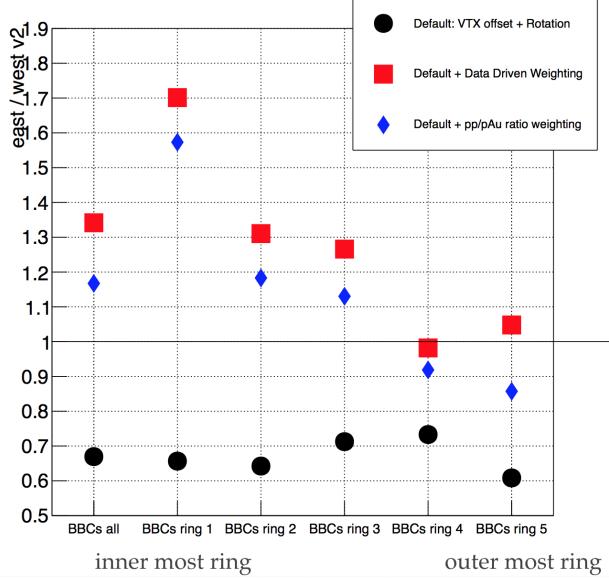

Figure 4.20: Plotted is the BBC correction summary where the y-axis is the east/west  $v_2$  ratio and the x-axis is the different subset of PMTs used to calculate the  $v_2$ . The black markers correspond to the default corrections. The red boxes correspond to the corrections with the analytic weighting shown in Fig 4.14. Finally, the blue diamonds correspond to the BBC inverse  $\phi$  charge weighting as shown in section 4.4.2. The first column is the quantity calculated from all PMTs. Columns 2 through 6 are using PMTs from certain rings as defined in Fig 4.7. Ring 1 is the hardest to correct. The first column should approximately be the average of all the other columns.

relative to  $v_2$  by varying the windows in the PC3 matching variables from  $3\sigma$  to  $2\sigma$ ; (2) many collisions occurring in the same bunch crossing, that occur at a rate of 8% in 0-5% central  $p$ +Au collisions. Low-luminosity and high-luminosity subsets of the data were analyzed, and the systematic uncertainty was determined to be  $^{+4\%}_{-0\%}$ , since the  $v_2$  was found to decrease in the events that contain a pile-up; (3) non-flow correlations which enhance the  $v_2$ , whose contribution we estimate from Fig. 4.24, assigning a  $p_T$ -dependent asymmetric uncertainty with a maximum value of  $^{+0\%}_{-23\%}$ ; (4) as discussed in the previous section, the beam alignment effects on the determination of  $\Psi_2$ . We assign a value of 5% for this systematic uncertainty by taking the difference of  $v_2$  when measured independently in the east and the west arms after applying the necessary corrections; (5) the difference in the  $v_2(p_T)$  values when measured independently using the BBCs and FVTXs event planes, which differ by  $\pm 3\%$ .

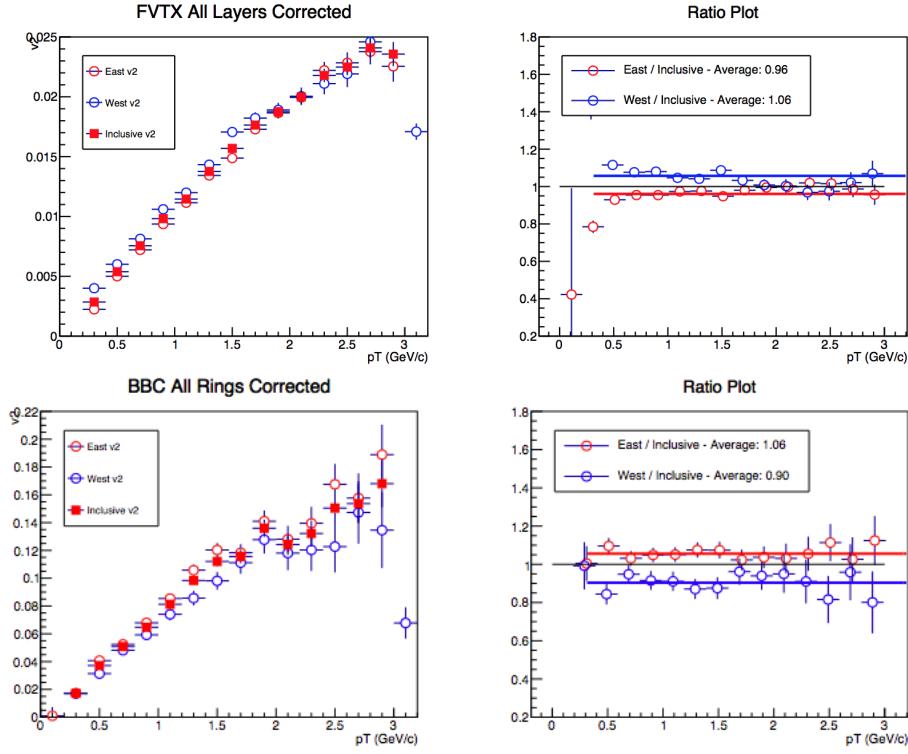

Figure 4.21: FVTXs  $v_2$  event plane measurement corrected with inverse  $\phi$  weighting and 20 % cut with FVTXs layer 3 is excluded (top) and BBCs  $v_2$  event plane measurement corrected with  $p+p/p+Au$  ratio weighting (bottom).

Table 4.5 summarizes of all these systematic uncertainties, categorized by type:

- (1) point-to-point uncorrelated between  $p_T$  bins,
- (2) point-to-point correlated between  $p_T$  bins,
- (3) overall normalization uncertainty in which all points are scaled by the same multiplicative factor.

#### 4.5.1 Effect of Event Pile-Up

Pile-up events occur when there are two or more collisions within the same bunch crossing.

Pile-up events are an issue for this analysis because they:

Table 4.5: Systematic uncertainties given as a percent of the  $v_2$  measurement. Note that the non-flow contribution is  $p_T$  dependent and the value here quoted corresponds to the highest measured  $p_T$ .

Source	Systematic Uncertainty	Type
Track Background	2.0%	1
Event Pile-up	$^{+4\%}_{-0\%}$	2
Non-Flow	$^{+0\%}_{-23\%}$	2
Beam Angle	5.0%	3
Event Plane Detectors	3%	3

- (1) are erroneously included into the 0-5% centrality selection due to two smaller collisions looking like a larger collision,
- (2) and reduce the value of  $v_2$  because the event plane angle from one collision will be different than the event plane angle in the other collision, such that correlations calculated by using particles produced from the two collisions are random and will dilute the real correlations, thereby reducing the flow signal.

In order to filter pile-up events we look at the distribution of BBC PMT timing values as seen in Fig 4.22. A normal event is strongly peaked at 0 while a pile-up event has a broad distribution and may not be centered at 0. We can come up with an algorithm to efficiently filter pile-up events by analyzing the BBC PMT timing value distribution event by event. When the  $v_2$  values are compared with and without the filter, a difference of 4% is seen.

#### 4.5.2 Effects of Non-Flow

Non-flow is a catch-all term used to categorize all types of long-range angular correlations which do not arise from hydrodynamic flow and are not related to the initial collision geometry. Non-flow constitutes a significant background to our measurement. There are several known sources of non-flow:

- (1) hard scattering events producing dijets

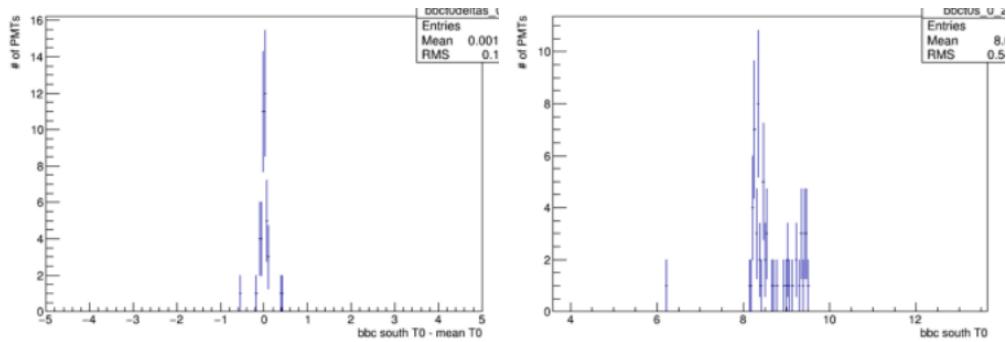

Figure 4.22: The distribution of BBC PMT timing values. The x-axis is the difference between the southern BBC PMT  $t_0$  - the mean  $t_0$  in the south. An example of a normal event (left) and an example pile-up event (right), are shown.

- (2) initial state correlations between target and projectile
- (3) decay chains of exotic particles
- (4) momentum conservation.

Fig 4.23 shows the characteristic two-particle correlations arising from non-flow associated with dijets. The near-side peak at  $(0,0)$  is from the cone of particles in a single jet all at a similar location in  $\eta$  and  $\phi$ . The away-side ridge around  $\phi = \pi$  originates from particles pairs, where each particle belongs to a different jet. The two jets are completely back-to-back in  $\Delta\phi$ , but have a spread in  $\Delta\eta$ . This correlation function yields a substantial  $c_2$  very similar to that from the hydrodynamic flow signal we are seeking. In order to minimize the contribution of dijet events, the standard flow analysis procedure is to select regions outside of the red dotted lines seen in Fig 4.23 ( $|\Delta\eta| > \eta_{min}$ , where  $\eta_{min}$  is usually of order 1.0 unit of pseudorapidity).

In order to estimate the degree of presence of non-flow, we can measure the  $c_2$  from p+p events which should be devoid of any hydrodynamic flow but should have many of the sources of non-flow present. In order to compare p+p with  $p+Au$ , we must scale-up the p+p quantity by the dilution factor defined in eq 4.22. The scaled down reference  $c_2$  is shown as blue squares in Fig. 4.24, panel (a). The ratio of  $c_2$  in the scaled-down p+p reference to that in  $p+Au$  is shown in panel (b).

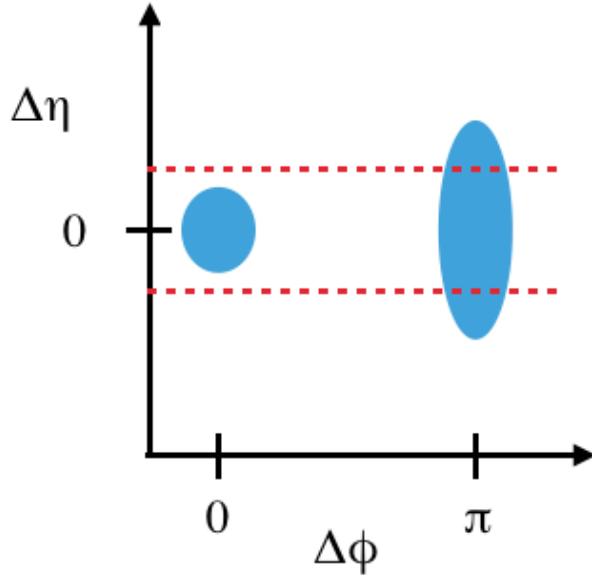

Figure 4.23: Plotted here is the 2D profile of a correlation function in  $\Delta\eta\Delta\phi$  space of a dijet event. The area in red dotted lines represent the exclusion zone in  $\Delta\eta$ , such that the measurement is made only using data from outside of the exclusion zone to reduce non-flow contributions.

From this ratio, as calculated in 4.22, it can be seen that the relative correlation strength in  $p+Au$  from elementary processes is at most 23% at the highest  $p_T$ . Since this procedure constitutes an approximation to quantify the non-flow correlation strength, it is not subtracted from the total signal, instead it is treated as a source of systematic uncertainty. Even though the  $p+Au$  and the  $p+p$  baseline data were collected in different years, such that potential changes in detector performance could affect our results, it was verified that using  $p+p$  data from various run periods has an effect of at most 3% on the calculated non-flow contribution.

$$c_2^{\text{pAu elementary}}(p_T) \simeq c_2^{p+p}(p_T) \frac{(\sum Q^{\text{BBC-S}})_{p+p}}{(\sum Q^{\text{BBC-S}})_{\text{pAu}}} \quad (4.22)$$

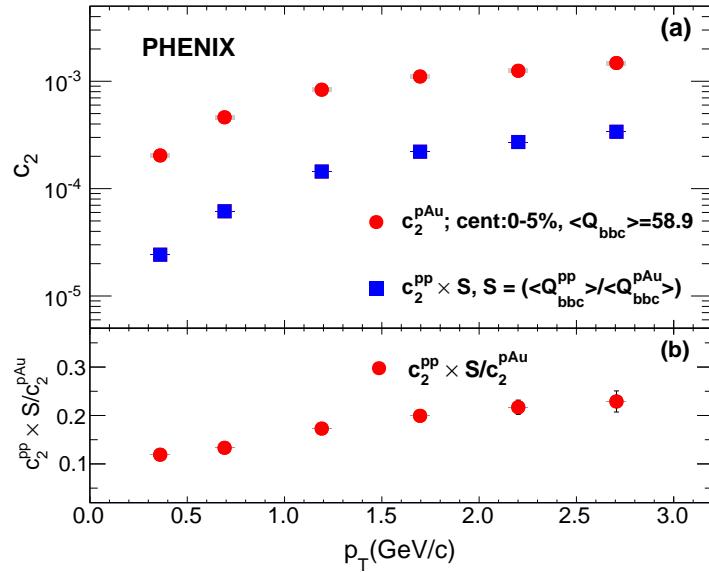

Figure 4.24: (a) The second order harmonic coefficients  $c_2(p_T)$  for long range angular correlations in 0%-5%  $p+\text{Au}$  collisions, as well as for minimum bias  $p+p$  collisions. The latter are scaled down by the factor  $(\sum Q^{\text{BBC-S}})_{p+p} / (\sum Q^{\text{BBC-S}})_{\text{pAu}}$ . (b) The ratio of the two harmonics is plotted with the corresponding statistical errors.

## Chapter 5

### Results and Discussion

The  $v_2$  measurement for  $p+\text{Au}$  at  $\sqrt{s_{NN}} = 200$  GeV 0–5% centrality completes the set of flow measurements in the small systems available at RHIC:  $p+\text{Au}$ ,  $d+\text{Au}$ , and  ${}^3\text{He}+\text{Au}$ . The goal of this set of measurements is to determine the effect of varying initial collision conditions on the resulting flow.

#### 5.1 $v_2$ Measurement

The resulting  $v_2$  measurement for  $p+\text{Au}$  at  $\sqrt{s_{NN}} = 200$  GeV 0–5% centrality is shown in Figure 5.1. The systematic uncertainty varies from  $^{+7.2}_{-13.4}\%$  at low  $p_T$  to  $^{+7.3}_{-23.8}\%$  at high  $p_T$ , where the asymmetric uncertainty is dominated by non-flow. The fact that the non-flow dominates the systematic uncertainty warrents further discussion on the treatment of non-flow.

##### 5.1.1 Non-flow Contribution

As was discussed in Section 4.4.2, the non-flow systematic uncertainty can instead be thought of as a systematic error that can be corrected for in our measurement. To further explore this non-flow effect, Figure 5.2 shows what the  $p+\text{Au}$  measurement looks like by subtracting the non-flow effect rather than treating it as an uncertainty. Due to non-flow being the dominant source of systematic uncertainty, the corrected  $p+\text{Au}$  points are nearly at the bottom of the systematic uncertainty boxes of the uncorrected points. The substantial changes this correction makes to the  $p+\text{Au}$  points, especially at high  $p_T$ , must be put in context of the field of heavy ion physics. This

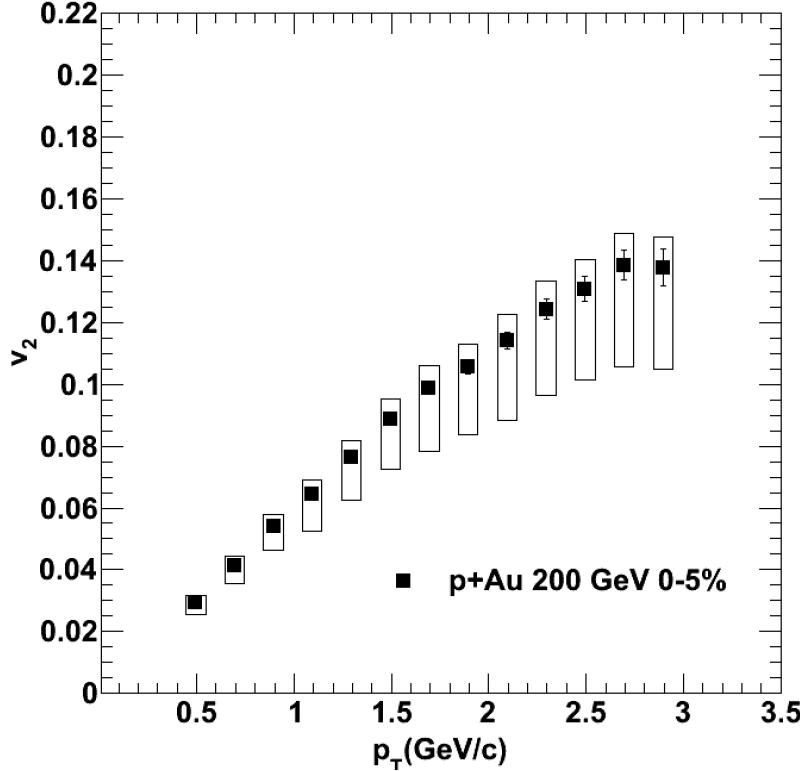

Figure 5.1: The  $v_2$  measurement of  $p+\text{Au}$  at  $\sqrt{s_{NN}} = 200$  GeV 0–5% centrality.

procedure to estimate the contribution of elementary processes to the measured  $v_2$  signal is an attempt at an accurate approximation. Although the non-flow approximation used in this thesis has its merits, there is currently no consensus in the field regarding how to properly quantify how much of the  $v_2$  corresponds to “flow” and how much corresponds to “non-flow.” Other experimental collaborations making flow measurements, such as STAR, ATLAS, and ALICE, treat non-flow in different ways **to add refs.** Therefore, we chose to explicitly state our methodology to estimate this non-flow and to treat it as a systematic effect that raises the measured  $v_2$ .

## 5.2 Comparison with Other Species at $\sqrt{s_{NN}} = 200$ GeV 0–5% Centrality

The substantial  $v_2$  in  $p+\text{Au}$  at  $\sqrt{s_{NN}} = 200$  GeV is interesting in itself but the significance of the measurement is best understood by comparing it to other small collision system results,

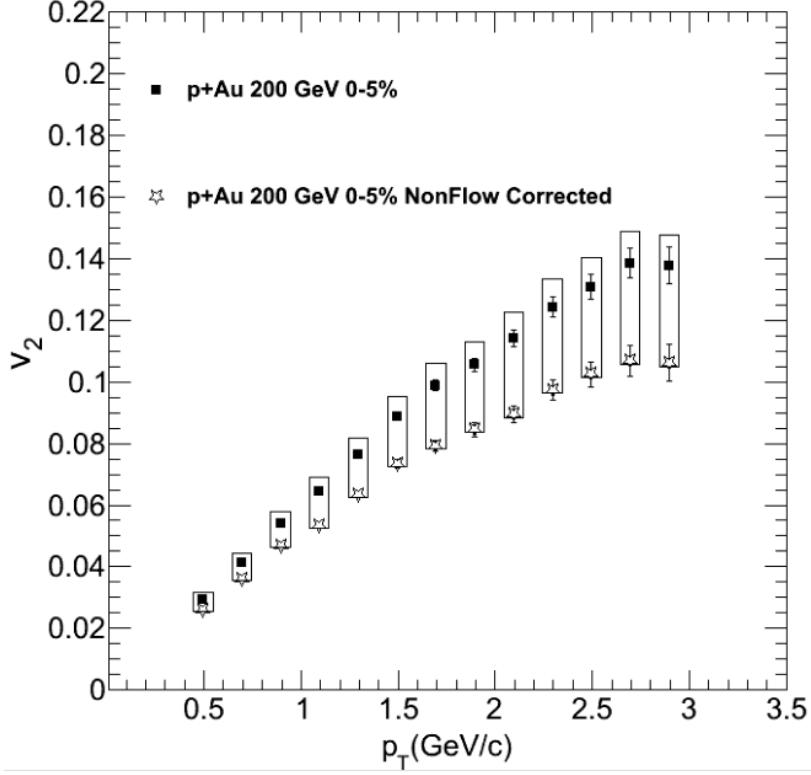

Figure 5.2: The  $v_2$  measurement of  $p+\text{Au}$  at  $\sqrt{s_{NN}} = 200$  GeV 0–5% centrality with the statistical and systematic errors corresponding to the bars and the boxes respectively. The stars are the same  $p+\text{Au}$  points but with the non-flow estimate subtracted rather than treated as a systematic uncertainty.

specifically  ${}^3\text{He}+\text{Au}$  [7] and  $d+\text{Au}$  [7] at the same  $\sqrt{s_{NN}}$  energy. In order to properly make the strongest physics statement possible in this comparison, we attempt to hold as many variables constant across all three datasets. Table 5.1 compares the various relevant parameters for the three collision species. As shown in the table, the FVTXs was not used in the  $d+\text{Au}$  measurement unlike for the  $p+\text{Au}$  and  ${}^3\text{He}+\text{Au}$  due to the fact that the FVTX was not installed in 2008 when the  $d+\text{Au}$  measurement was taken. The table also highlights the fact that  $dN_{ch}/d\eta$ , the  $\eta$  dependence of the charged particle multiplicity, has not been measured in  $p+\text{Au}$   $\sqrt{s_{NN}} = 200$  GeV, in contrast to  ${}^3\text{He}+\text{Au}$  and  $d+\text{Au}$ . This fact is relevant because mid-rapidity  $dN_{ch}/d\eta$  is an input to the SONIC model for the purposes of multiplicity matching, as discussed in the next section. Among the differences across the columns, the largest is the lack of a non-flow estimate for the  $d+\text{Au}$  dataset.

In the interest of measurement compatibility, and for the reason stated in the previous section, there is no non-flow correction applied to any of the datasets.

Table 5.1: Dataset Variables Comparison listed in order: center of mass energy per nucleon, centrality, mid-rapidity charged particle multiplicity per unit of psuedo-rapidity from [6], year, trigger (as defined in section 2.2.4) particle sample, trigger particle acceptance, event plane determination,  $\Psi_2$  Resolution, condition of available non-flow estimate.

Variable	$p+\text{Au}$	$d+\text{Au}$	${}^3\text{He}+\text{Au}$
$\sqrt{s_{NN}}$ (GeV)	200	200	200
Centrality	0–5%	0–5%	0–5%
Mid-rapidity $dN_{ch}/d\eta$	N/A	$20.8 \pm 1.5$	$26.3 \pm 1.8$
Year (collected)	2015	2008	2014
Trigger Particle Sample	Charged Hadrons	Charged Hadrons	Charged Hadrons
Trigger Particle Acceptance	$ \eta  < 0.35$	$ \eta  < 0.35$	$ \eta  < 0.35$
Event Plane	$-3 < \eta < -1$ (FVTXs)	$-3.7 < \eta < -3.1$ (MPCs)	$-3 < \eta < -1$ (FVTXs)
$\Psi_2$ Resolution	0.171	0.14	0.274
Non-flow Estimate	yes	no	yes

Figure 5.3 shows the  $v_2(p_T)$  measurements in the three systems. All three measurements exhibit substantial  $v_2$  values that rise as a function of  $p_T$  with a similar shape. Within the error bars of each measurement, the  ${}^3\text{He}+\text{Au}$  and  $d+\text{Au}$  measurements agree and the  $p+\text{Au}$  measurement is substantially lower. This effect is especially clear at low  $p_T$ , where bulk effects would be most dominant. In order to understand the significance of this set of measurements, comparison to standard theoretical models are useful.

### 5.3 Comparison with Theory

Figure 5.4 shows  $v_2(p_T)$  for the three systems and  $v_2(p_T)$  calculations for each system from the SONIC hydrodynamic model [28], which incorporates standard Monte Carlo Glauber initial conditions followed by viscous hydrodynamics with  $\eta/s = 0.08$ , and a transition to a hadronic cascade at  $T = 170$  MeV<sup>1</sup>. It is notable that these calculations for each system are matched to the charged particle density at mid-rapidity, with the exact values for 0–5% centrality of 10.0, 20.0, and

<sup>1</sup> Note: please reference Chapter 2 for an in depth discussion about the theoretical models of SONIC, SuperSONIC, IP-Glasma, MC Glauber, and AMPT.

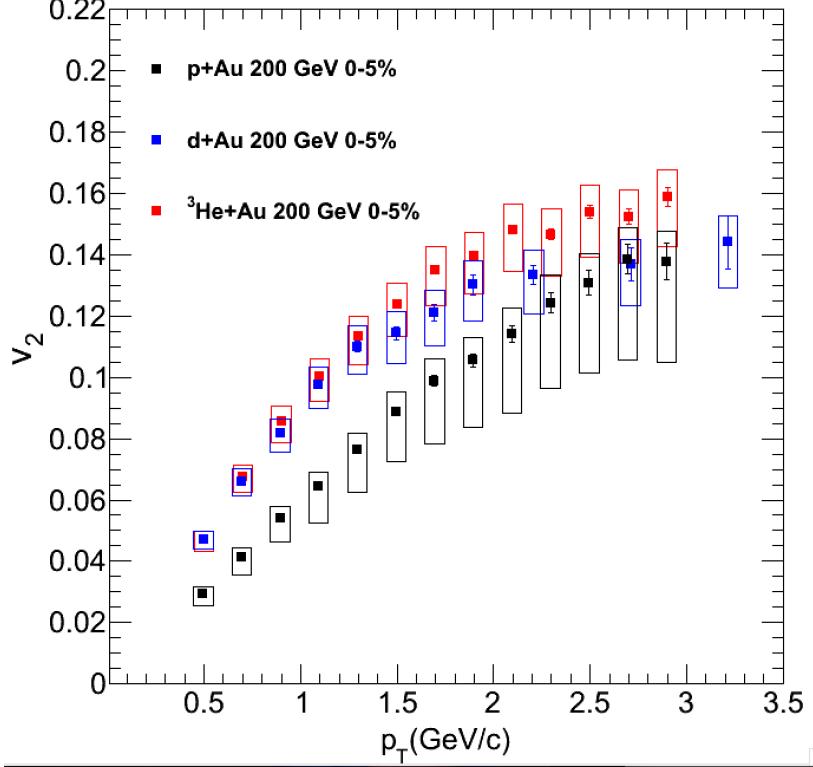

Figure 5.3:  $v_2$  of charged hadrons within  $|\eta| < 0.35$  in 0–5%  $p+\text{Au}$  compared to calculations using the SONIC model match to the same multiplicity as the data. The model calculations have good agreement with the center of the systematic uncertainty bars.

27.0, for  $p+\text{Au}$ ,  $d+\text{Au}$ , and  $^3\text{He}+\text{Au}$  collisions, respectively [28]. As mentioned above, the  $dN_{cn}/d\eta$  has not been measured for  $p+\text{Au}$ , and the value of 10.0 was extrapolated from measurements in the other two systems [28]. The SONIC calculation includes both the geometry-related change in the initial conditions and the relative collision multiplicity for the three systems. In all these cases, a good agreement is seen within the systematic uncertainties between the data and the calculation. This agreement between data and hydrodynamic calculation alone strongly supports the notion of initial geometry coupled to the hydrodynamic evolution of the medium as a valid framework to understand small system collectivity.

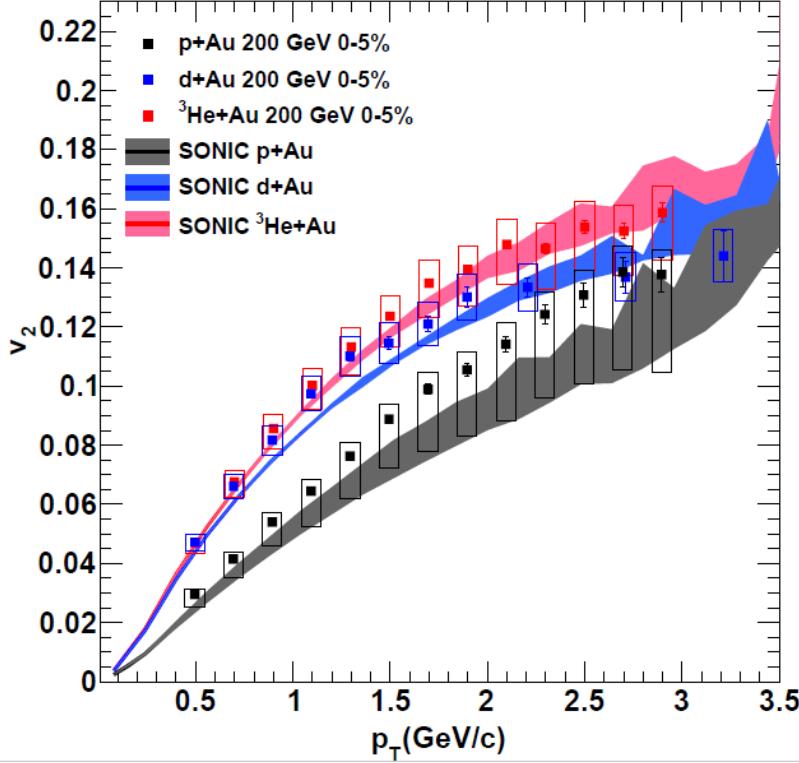

Figure 5.4:  $v_2$  of charged hadrons within  $|\eta| < 0.35$  in 0–5%  $p$ +Au,  $d$ +Au, and  $^3\text{He}+\text{Au}$  central collisions, compared to hydrodynamic calculations using the SONIC model, matched to the same multiplicity as the data. Note that the data points shown include non-flow contributions, whose estimated magnitude is accounted for in the asymmetric systematic uncertainties.

### 5.3.1 Initial Conditions and Eccentricity

In order to better understand the comparison of the three systems, a deeper understand of the initial conditions is warranted. One critical quantity to characterize the initial collision symmetry is known as the eccentricity. As mentioned in Chapter 2, the second order eccentricity,  $\varepsilon_2$ , can be calculated from the distribution of the nucleons involved in the initial collision as:

$$\varepsilon_2 = \frac{\sqrt{\langle r^2 \cos(2\phi) \rangle^2 + \langle r^2 \sin(2\phi) \rangle^2}}{\langle r^2 \rangle}, \quad (5.1)$$

where  $r$  is the radial nucleon position relative to the centroid of the participants and  $\phi$  is the azimuthal angle of the nucleons [11].

The significance of  $\varepsilon_2$  is that  $v_2$  should be proportional to  $\varepsilon_2$  if the  $v_2$  is primarily from elliptical flow. Table 5.2 shows  $\varepsilon_2$  calculations from the MC Glauber and IP-Glasma models. The  $\varepsilon_2$  values can be understood by looking the top three panels of Figure 5.5 which show the spatial distribution of the energy density of the collisions for the  $p+\text{Au}$ ,  $d+\text{Au}$ , and  $^3\text{He}+\text{Au}$  from left to right. It is note worthy that the eccentricities of  $d+\text{Au}$  and  $^3\text{He}+\text{Au}$  collisions are largely based on relative nucleon orientation, where as the initial condition of  $p+\text{Au}$  is solely based on the shape of the lone proton projectile and any fluctuations in the target gold nucleus. Table 5.2 illustrates the uniqueness of the  $p+\text{Au}$  system by showing the diverging values of  $\varepsilon_2$  which can be calculated by IP-Glasma and MC Glauber. Unlike MC Glauber, IP-Glasma generates very circular initial conditions for  $p+\text{Au}$ , which correspond to very small  $\varepsilon_2$  values. For  $d+\text{Au}$  and  $^3\text{He}+\text{Au}$ , the presence of multiple hot spots wash out differences in single nucleon initial conditions, and thus IP-Glasma and MC-Glauber agree at the 10% level.

While the top three panels of Figure 5.5 are example initial energy density distributions for the three systems, the bottom three panels are the system's energy density distributions after a medium has been formed and time evolved hydrodynamically. For the cases of  $d+\text{Au}$  and  $^3\text{He}+\text{Au}$ , the initial hot spot orientation is translated into an inverted orientation. This is due to the fact that the medium is produced with the highest energy density at places where the expanding hotspots overlap. The expanding hotspots create a substantial final state elliptical flow with an event plane angle relative to the spatial orientation of the initial hotspots. For example, in the  $d+\text{Au}$  collision, the event plane vector is transverse to the line that connects the deuteron's nucleons.

Table 5.2: Initial eccentricity  $\varepsilon_2$  of small systems at  $\sqrt{s} = 200$  GeV for 0–5% centrality from Monte Carlo Glauber initial conditions smeared with a two-dimensional Gaussian of width  $\sigma = 0.4$  fm, and IP-Glasma initial conditions.

	$p+\text{Au}$	$d+\text{Au}$	$^3\text{He}+\text{Au}$
Glauber $\langle \varepsilon_2 \rangle$	$0.23 \pm 0.01$	$0.54 \pm 0.04$	$0.50 \pm 0.02$
IP-Glasma $\langle \varepsilon_2 \rangle$	$0.10 \pm 0.02$	$0.59 \pm 0.01$	$0.55 \pm 0.01$

Figure 5.6 gives insight into the relation between initial collision eccentricities, as defined in

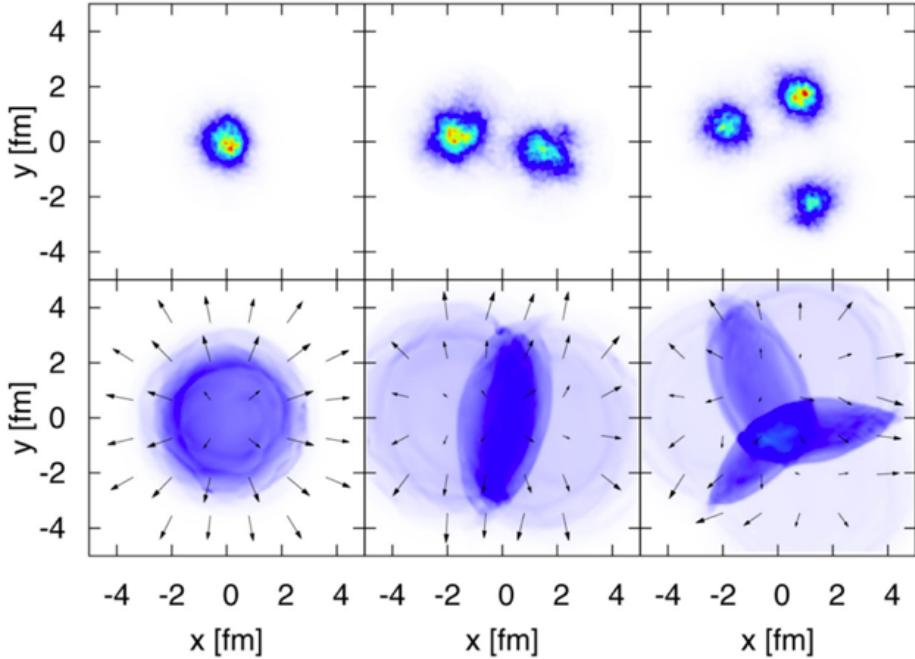

Figure 5.5: The top three panes show the transverse spatial locations of the initial hot spots of the three collision species,  $p+\text{Au}$ ,  $d+\text{Au}$ , and  $^3\text{He}+\text{Au}$  respectively. The bottom three plots show the resulting medium produced from the overlapping hot spots as well as the resulting particle momentum vector field as calculated from a hydrodynamic model, calculation details in [52]

Equation 5.1, as they are transformed into final state flow. The plot was produced by running many events for  $p+\text{Au}$ ,  $d+\text{Au}$ , and  $^3\text{He}+\text{Au}$  systems with different initial spatial distribution smearing (i.e. different  $\varepsilon_2$ ). The final freeze-out hyper-surface of each event is then translated into a distribution of hadrons via the Cooper-Frye freeze-out technique [18]. Figure 5.6 shows the pion  $v_2$  at  $p_T = 1.0$  GeV/c divided by  $\varepsilon_2$  as a function of  $\varepsilon_2$  for each individual  $p+\text{Au}$ ,  $d+\text{Au}$ , and  $^3\text{He}+\text{Au}$  event. The figure shows a reasonably common scaling of  $v_2/\varepsilon_2$  for all three systems with the  $d+\text{Au}$  and  $^3\text{He}+\text{Au}$  simply extending to larger eccentricities. There are a small set of events with very large  $\varepsilon_2$ , but have a rather small final  $v_2$ . Examination of these events reveals them to be  $d+\text{Au}$  events where the two hot spots are so far apart that the hydrodynamic fluids never connect during the time evolution, as seen in the overlay in Figure 5.6, in order to produce nearly any elliptic flow. There are fewer  $^3\text{He}+\text{Au}$  in this category, seen where two nucleons are very close

and the third is quite far away, again having the same effect.

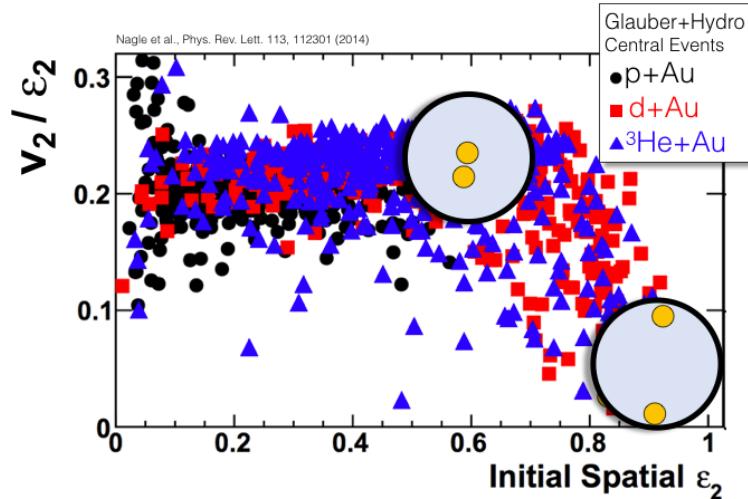

Figure 5.6:  $v_2/\varepsilon_2$  versus  $\varepsilon_2$  with the flow coefficient for pions evaluated at  $p_T = 1.0$  GeV/c from  $p$ +Au,  $d$ +Au, and  $^3\text{He}$ +Au central ( $b < 2$  fm) events (which roughly corresponds to 0–5% centrality). The results are with input parameters  $\eta/s = 1/4\pi$  and initial Gaussian smearing  $\sigma = 0.4$  fm and a freeze-out temperatures of  $T_F = 150$  MeV. Diagrams of two possible  $d$ +Au initial configurations are overlayed on top of the plot. Increasing distance between the two  $d$ +Au nucleons correspond to a larger  $\varepsilon_2$  [40].

To further explore the effect of initial conditions on our  $v_2$  measurement, we divide the  $v_2$  curves by their corresponding  $\varepsilon_2$  from Table 5.2, attempting to establish a scaling relation between the two quantities. In ideal ( $\eta/s = 0$ ) hydrodynamics with long lived systems  $v_2/\varepsilon_2$  should be independent of  $\varepsilon_2$ . Figure 5.7 shows that the ratios do not collapse to a common value. As expected, this behavior is also reproduced by the SONIC calculation, because both data and calculation are divided by the same  $\varepsilon_2$  values. The lack of scaling in the SONIC calculation can be understood from  $d$ +Au events where the neutron and proton from the deuteron projectile are far separated and create two hot spots upon impacting the Au nucleus, as seen in Figure 5.6. These events have a large  $\varepsilon_2$ , but can result in small  $v_2$  if the two hot spots evolve separately, never combining within the hydrodynamic time evolution. This effect is present in the  $d$ +Au and  $^3\text{He}$ +Au systems, and lowers the average  $v_2/\varepsilon_2$  as detailed.

Although, MC Glauber and IP-Glasma are the established models for calculating initial

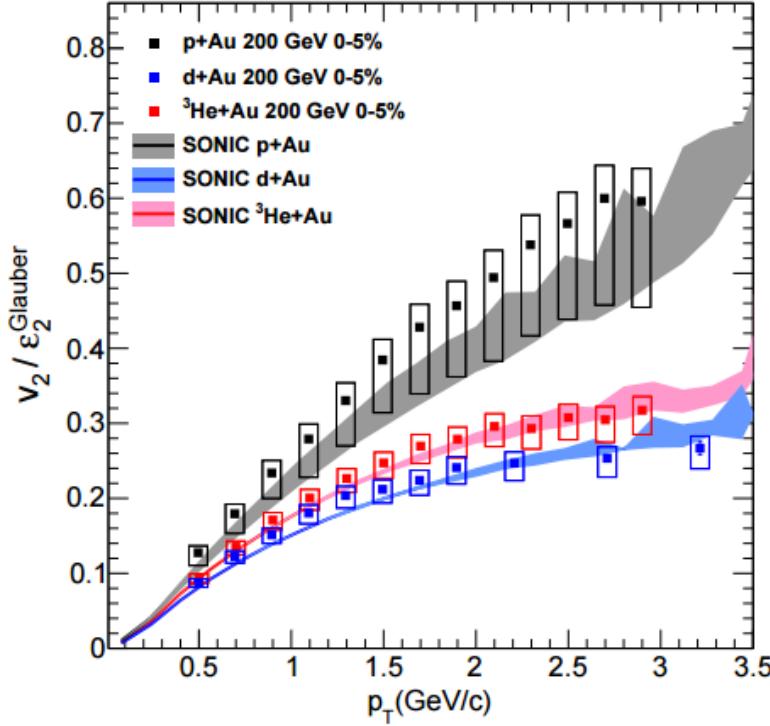

Figure 5.7:  $v_2$  of charged hadrons within  $|\eta| < 0.35$  in 0–5%  $p+\text{Au}$ ,  $d+\text{Au}$ , and  $^3\text{He}+\text{Au}$  central collisions, divided by their corresponding eccentricity  $\varepsilon_2$  from Glauber calculations, compared to SONIC calculations of the same quantity. Note that the data points shown include non-flow contributions, whose estimated magnitude is accounted for in the asymmetric systematic uncertainties.

conditions in this context, new models for calculating the initial conditions are promising. A model for initial conditions which incorporates more degrees of freedom by extending the Monte Carlo Glauber approach to also incorporate collisions between constituent quarks, basically increasing the granularity of the simulation [20]. In the rightmost panel of Figure 5.8, the initial eccentricities  $\varepsilon_2$  in  $p+\text{Au}$ ,  $d+\text{Au}$ , and  $^3\text{He}+\text{Au}$  obtained by incorporating constituent quarks, in addition to multiplicity fluctuations, are found to be  $\varepsilon_2 = 0.42$ ,  $0.54$ , and  $0.54$ , respectively. This calculation assumes a Gaussian density distribution of low- $x$  gluons around each constituent quark, of width  $\sigma_g = 0.3$  fm. The  $\varepsilon_2$  of  $d+\text{Au}$  and  $^3\text{He}+\text{Au}$  systems show minimal sensitivity to the incorporation of constituent quarks and multiplicity fluctuations. However,  $p+\text{Au}$  has a substantially larger  $\varepsilon_2$  than in the models shown in Table 5.2 when incorporating these effects. Another attempt at the

calculation incorporating constituent quarks and multiplicity presents calculations in which case a lower  $\varepsilon_2 = 0.34$  is obtained for  $p+\text{Au}$  [58]. This result shows that when compared to the Glauber  $\varepsilon_2$  for  $p+\text{Au}$  in Table 5.2, quark-level degrees of freedom and multiplicity fluctuations may both play a significant role. In addition to the constituent MC Glauber, it is worth mentioning that an intriguing method for understanding the initial conditions in  $p+\text{Au}$  comes from fluctuations of the shape of the proton, as described in Ref. [53].

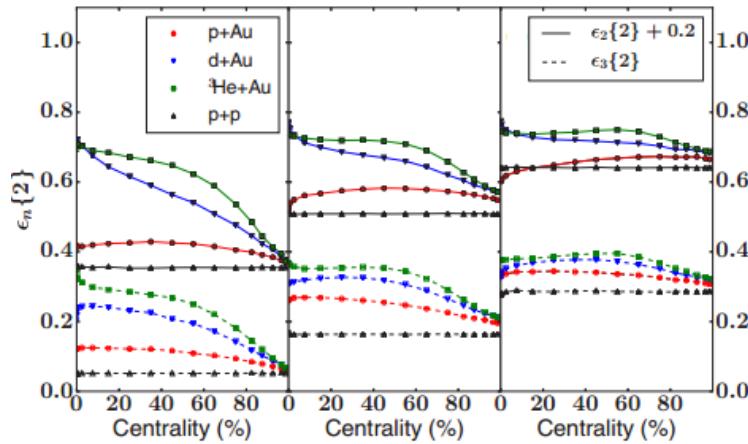

Figure 5.8: Centrality dependence of  $\varepsilon_2$  calculated in a variety of small collision systems with a variety of models for collision detection [disklike (left), Gaussian (middle), quark-subdivided nucleons with  $\sigma_g = 0.3$  fm (right)] [58].

### 5.3.2 Comparison to Alternative Models

Although hydrodynamic models like SONIC, which incorporate MC Glauber plus relativistic hydrodynamics, are the standard in which elliptical flow is understood in the field of heavy ions, it is important to test the consistency of other models with our data. Figure 5.9 depicts the measured  $v_2(p_T)$  data curves with four different model comparisons. Theoretical predictions are available in the literature, most notably from hydrodynamics with Glauber initial conditions (SONIC [27] and SuperSONIC [49]), hydrodynamics with IP-Glasma initial conditions [52], and A-Multi-Phase-Transport Model (AMPT) [35]. The SuperSONIC model uses the same technique for initial conditions, hydrodynamic expansion, and hadronic cascade as SONIC, yet additionally incorporates

pre-equilibrium dynamics with a calculation in the framework of the AdS/CFT correspondence [56].

As mentioned in Chapter 2, calculations using IP-Glasma initial conditions followed by viscous hydrodynamics have been successfully used to describe collectivity in A+A collisions, so it is reasonable to apply IP-Glasma to  $v_2$  in small systems. For the model of IP-Glasma+Hydro, in the case of  $d+\text{Au}$  and  ${}^3\text{He}+\text{Au}$ , a better agreement with data can be achieved by increasing the value of  $\eta/s$  or by including a hadronic cascade stage. However, doing so would lower the prediction for  $p+\text{Au}$  even further. This demonstrates that IP-Glasma does not generate the appropriate initial conditions to account for measured  $v_2$  via hydrodynamic flow.

SONIC and SuperSONIC both agree well with the data of all three systems, although the agreement with the  $p+\text{Au}$  points only agrees within in the large systematic uncertainty bars. As mentioned above, the agreement of hydrodynamic models supports the idea of initial geometry as the driver of the  $v_2$  signal. Additionally, the three different initial geometries provided by the datasets are useful in constraining the parameters in the SONIC and SuperSONIC models such as  $\eta/s$ , the transition temperature to a hadron cascade, and the Monte Carlo Glauber smearing of nucleon coordinates of  $\sigma = 0.4$  fm.

Finally, AMPT, as described in Chapter 2, combines partonic and hadronic scattering in a single model. Central AMPT events with impact parameter  $b < 2$  have a midrapidity  $dN_{ch}/d\eta = 8.1, 14.8,$  and  $20.7$  for  $p+\text{Au}$ ,  $d+\text{Au}$ , and  ${}^3\text{He}+\text{Au}$ , respectively. AMPT uses the same Monte Carlo Glauber initial conditions used to characterize event geometry as in SONIC or SuperSONIC. However, AMPT makes use of the initial Glauber geometry information to compute  $v_2$  relative to the participant plane [42]. AMPT yields results that agree reasonably well with the data below  $p_T \approx 1$  GeV/c, yet under predict them at higher  $p_T$ . Although AMPT does not describe the data as well as SONIC, AMPT has successfully been applied to a variety of systems at RHIC and the LHC [37].

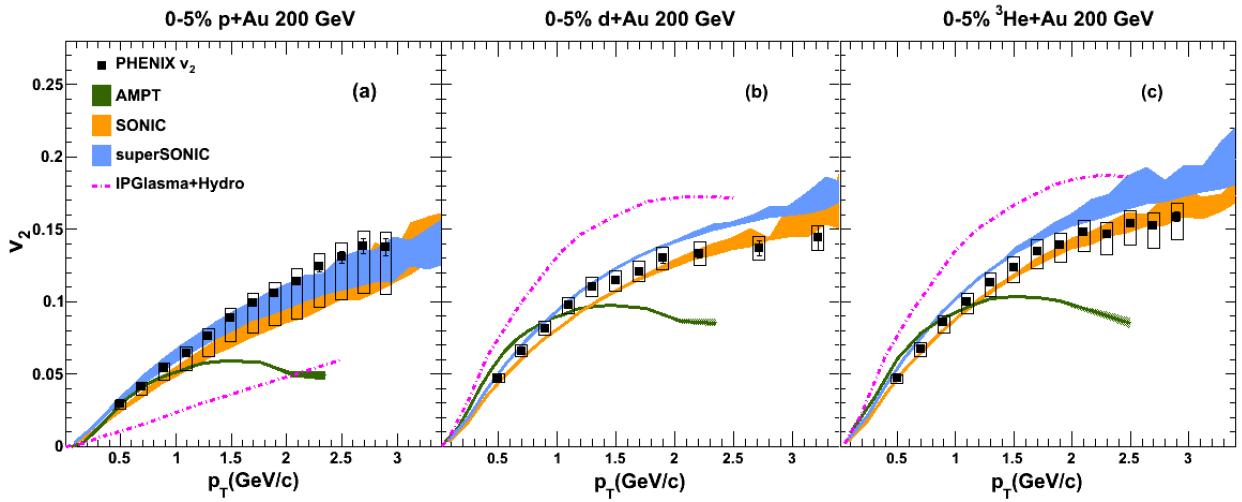

Figure 5.9: Transverse momentum dependence of  $v_2$  in central 0–5% (a)  $p$ +Au, (b)  $d$ +Au, and (c)  ${}^3\text{He}+\text{Au}$  collisions at  $\sqrt{s_{NN}} = 200$  GeV. Theoretical calculations from AMPT, SuperSONIC, and IP-Glasma+Hydro are shown in each panel. Note that the data points shown include non-flow contributions, whose estimated magnitude is accounted for in the asymmetric systematic uncertainties.

## Chapter 6

### Summary and Outlook

We have measured the elliptic flow in 0–5% centrality  $p+\text{Au}$  collisions at  $\sqrt{s_{NN}} = 200$  GeV.

We quantify the elliptic flow by measuring the second-order flow coefficient  $v_2$  defined as:

$$v_2 = \frac{\langle \cos 2(\phi - \Psi_2) \rangle}{\text{Resolution}(\Psi_2)}, \quad (6.1)$$

where  $\phi$  is the azimuthal of charged hadrons at mid rapidity,  $\Psi_2$  is the second-order event plane determined at backwards rapidity (Au-going direction), and  $\text{Resolution}(\Psi_2)$  is the event plane resolution. This procedure is detailed in Chapter 4, Section 4.2.1.

The measurement of  $v_2(p_T)$  in 0–5% centrality  $p+\text{Au}$  at  $\sqrt{s_{NN}} = 200$  GeV collisions completes a set of measurements with engineered initial geometries at RHIC, including the  $p+\text{Au}$ ,  $d+\text{Au}$ , and  $^3\text{He}+\text{Au}$  as shown in Figure 6.1. Sources of systematic uncertainty have been described in detail in Chapter 4, Section 4.5, with the non-flow being the dominant source of systematic uncertainty. The measured  $v_2(p_T)$  in  $p+\text{Au}$  at  $\sqrt{s_{NN}} = 200$  GeV is in agreement with Monte Carlo Glauber initial conditions plus relativistic hydrodynamics (SONIC), which can be seen on the plot. This agreement of  $v_2$  with a hydrodynamic model is an indication that the initial state geometry becomes transformed into a final state momentum anisotropy in 0–5%  $p+\text{Au}$  at  $\sqrt{s_{NN}} = 200$  GeV collisions.

In order to properly compare the  $v_2$  of  $p+\text{Au}$ ,  $d+\text{Au}$ , and  $^3\text{He}+\text{Au}$  at  $\sqrt{s_{NN}} = 200$  GeV, for each system we have compared the average second-order eccentricity  $\varepsilon_2$  of the initial collision, as defined in Chapter 5, Section 5.3.1. If the measured  $v_2$  is primarily from hydrodynamic flow, i.e. minimal levels of non-flow, then  $v_2 \propto \varepsilon_2$ . Thus, the Monte Carlo Glauber  $\varepsilon_2$  for  $p+\text{Au}$ ,  $d+\text{Au}$ , and

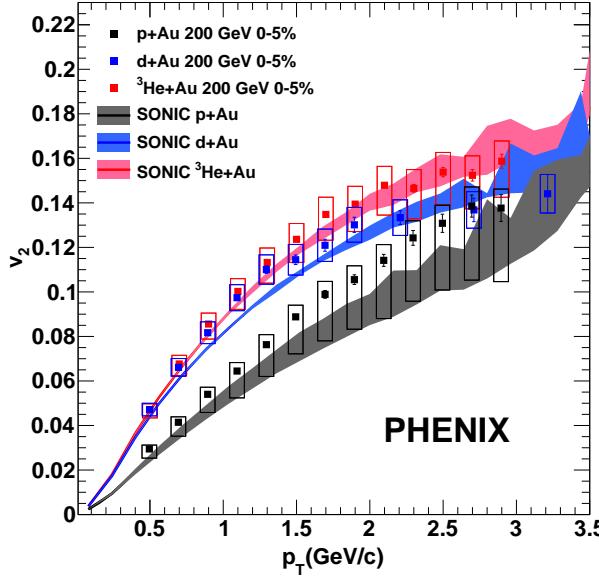

Figure 6.1:  $v_2$  of charged hadrons within  $|\eta| < 0.35$  in 0–5% centrality  $p+\text{Au}$ ,  $d+\text{Au}$ , and  $^3\text{He}+\text{Au}$  at  $\sqrt{s_{NN}} = 200$  GeV events, compared with hydrodynamic calculations using the SONIC model, matched to the same multiplicity as the data [28].

$^3\text{He}+\text{Au}$  being 0.23, 0.54, and 0.50, respectively, implies the ordering of  $v_2$  of the three systems should be  $v_2^{d+\text{Au}} \approx v_2^{^3\text{He}+\text{Au}} > v_2^{p+\text{Au}}$  which is what is observed in Figure 6.1.

Future work is being done in analyzing the small collision systems recently run (in 2016) at RHIC:  $d+\text{Au}$  at  $\sqrt{s_{NN}} = 200$ , 62, 39, and 20 GeV. By measuring the elliptic flow in this  $d+\text{Au}$  beam energy scan, information on the effect of varying the initial temperature and the lifetime of the medium can be obtained. It is noteworthy that even at low  $\sqrt{s_{NN}}$  for  $d+\text{Au}$  collisions, hydrodynamic simulations determine that the space-time volume of QGP is not negligible, as shown in Figure 6.2. In fact, the calculated space-time volume of the medium at  $\sqrt{s_{NN}} = 20$  GeV is roughly half of the calculated space-time volume for  $\sqrt{s_{NN}} = 200$  GeV, indicating that there is a reasonable expectation to see some evidence of a QGP medium forming in  $d+\text{Au}$  collisions at  $\sqrt{s_{NN}} = 20$  GeV, if the hydrodynamic model picture still applies at the lower energy.

Predictions have been made of the  $v_2$  for the various energies of the  $d+\text{Au}$  beam energy scan by using the SONIC, SuperSONIC, and AMPT models, which are described in Chapter 2.

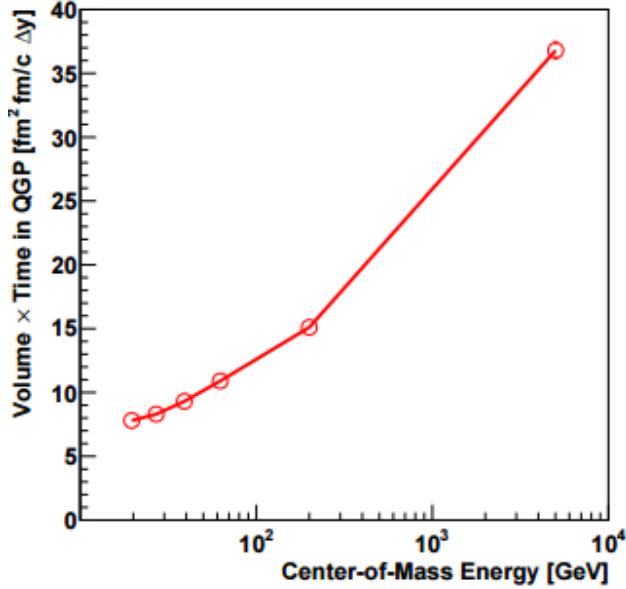

Figure 6.2: The total space-time volume as a function of  $\sqrt{s_{NN}}$  in heavy ion collisions calculated by a hydrodynamic model [34].

Figure 6.3 shows the model prediction curves of  $v_2$  in the four different energies. The SONIC and SuperSONIC model, the hydrodynamic models, both predict that there will be a sizable  $v_2$  in all of the  $\sqrt{s_{NN}}$  systems which has a positive  $\sqrt{s_{NN}}$  energy dependence across all  $p_T$ . AMPT, a non-hydrodynamic model, predicts a similarly large  $v_2$  across the different energies with only a modest  $\sqrt{s_{NN}}$  dependence for  $p_T \approx 1.0$  GeV/c and less. The discrepancy between the SONIC and SuperSONIC  $v_2$  and the AMPT  $v_2$  at  $p_T > 1.0$  GeV/c is further explored in Ref. [34]. The future measurement of elliptic flow in the  $d$ +Au beam energy scan datasets along with the measurement of the completion of the set of three measurements made in this thesis furthers our understanding of the phenomena of QGP in small collision systems.

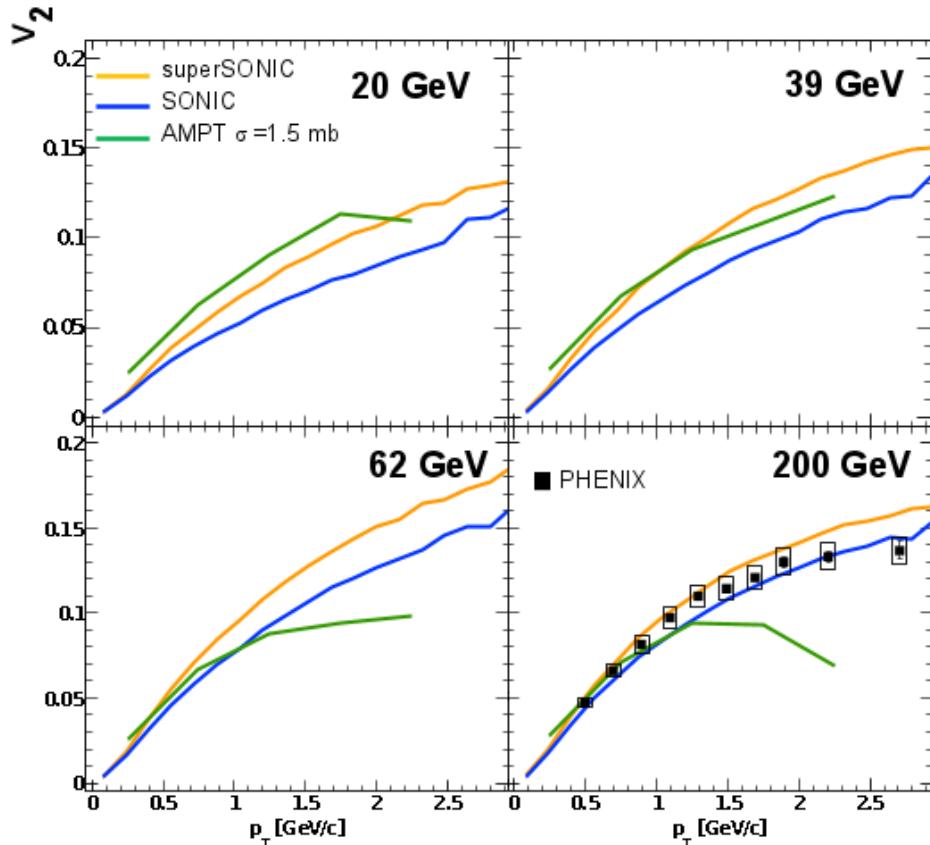

Figure 6.3: Calculations of  $v_2(p_T)$   $d+Au$  events at various  $\sqrt{s_{NN}}$  (given on the upper right of each panel) for AMPT, SONIC, and Supersonic models. Note that there are data points in the lower right panel due to the fact that the  $v_2$  in  $d+Au$  at  $\sqrt{s_{NN}} = 200$  GeV has been measured previously by PHENIX from data taken in 2008 [34].
